It has been found by observation that even when the moon is totally immersed in the earth's shadow she still continues to be visible, her surface being distinguishable by a dull copper colour. This is occasioned by the light passing through the terrestrial atmosphere being refracted so as to fall on the moon's surface. The ruddy colour of the moon is due to the absorption of the violet rays by the terrestrial atmosphere. The colour of the moon's surface during an eclipse is subject to considerable variations. Sometimes the degree of obscuration is very slight; on other occasions it is so great that the moon ceases to be visible. Generally, it may be stated that the colour of the moon's surface will depend on the condition of the earth's atmosphere at the time of the eclipse.

LUNAR EVECTION. An inequality in the moon's longitude, occasioned by the disturbing force of the sun. It depends on the variable excentricity of the lunar orbit and the moveable position of the apsides. The discovery of this inequality is due to Ptolemy. For an explanation of its physical cause, see GRAVITATION.

LUNAR OBSERVATION generally means an observation of the moon's distance from a star, for the purpose of finding the longitude. [LONGITUDE AND LATITUDE, METHODS OF FINDING.]

LUNAR THEORY. By the theory of a planet is meant the deduction of its motion from the law of gravitation. This subject is

discussed in the article GRAVITATION. For the numerical data see MOON.

LUNATIC ASYLUMS. In every civilised country the necessity of at least guarding against any calamitous result from the loss of reason in any of the members of society, must have been a serious consideration. In the East, idiots or harmless lunatics are considered as holy, and are usually provided for by the benevolent, but no public care seems to be bestowed even on the more violent. The buildings in cemeteries are often the abodes of such sufferers. Mr. Warburton ('Crescent and Cross,' ii. 352) states, that when travelling in Lebanon, and near a Moslem village, "the silence of the night was now broken by fierce yells and howlings, which I discovered proceeded from a naked maniac, who was fighting with some wild dogs for a bone." This madman, on being disturbed, made an attack on Mr. Warburton. Unfortunately, it appears to have been taken for granted that such maladies were incurable, and coercion and confinement were the chief appliances used in all cases where any restraint appeared necessary. Even Shakspeare makes Rosalind say, "a dark house and a whip" are what madmen deserve; and Malvolio is to be had "in a dark house and bound." When they were supposed to be harmless, lunatics and idiots were suffered to wander about the country, trusting to precarious charity, and subjected to occasional whippings. These provisions, such as they were, became manifestly insufficient, and asylums were sparingly provided, where probably the worst cases were received. But though shelter was thus given, the treatment did not greatly vary. It was still the dark house and the whip. The system pursued was always one of coercion and severity, too frequently of cruelty. In the old hospital of Bethlem in Moorfields, London, the poor lunatics were made a show of, as if they had been wild beasts, and the miserable patients were excited to rage to render the exhibition more stimulating. Henry Mackenzie, in his 'Man of Feeling,' published in 1771, describes with other sensations a visit to this place. "Their conductor led them first to the dismal mansions of those who are in the most horrible state of incurable madness. The clanking of chains, the wildness of their cries and the imprecations which some of them uttered, formed a scene inexpressibly shocking. Harley and his companions, especially the female part of them, begged their guide to return: he seemed surprised at their uneasiness, and was with difficulty prevailed on to leave that part of the house without showing them some others; who, as he expressed it, in the phrase of those that keep wild beasts for show, were much better worth seeing than any they had passed, being ten times more fierce and unmanageable." Mackenzie makes Harley observe, "I think it an inhuman practice to expose the greatest misery with which our nature is afflicted, to every idle visitant who can afford a trifling perquisite to the keeper; especially as it is a distress which the humane must see with the painful reflection that it is not in their power to alleviate it." The last plate of Hogarth's 'Rake's Progress,' of a date a few years earlier, gives even a more vivid picture of a madhouse of the period. Nearly naked, in chains, his head shaved, in a dirty straw-littered cell, and wildly raging; "a monumental figure over the grave of his reason," as Lichtenberg, the German commentator on Hogarth, expresses it, the poor maniac is yet exhibited by his stern-looking keeper. Still the system was continued; thousands went to see, hundreds perhaps to pity, but none to remedy. The only approximation was, that this shameful exhibition was prohibited in 1771.

Such scenes were not peculiar to England. They could have been paralleled, perhaps exceeded, in every state throughout Europe. But relief was approaching, and it began in France.

The benevolent and courageous Pinel was the first to attempt the restoration of the insane to a position among human beings. The scene of his exertions, which were the first great step of the non-restraint system, was the Bicêtre—a hospital for insane men, near Paris. In this frightful prison the universal practice was to load patients with heavy chains, which remained on for the remainder of their lives, and to immure them in dark, unwarmed, and unventilated cells. Pinel determined on at once releasing a large number of patients. The following account of the experiment is extracted from the 'British and Foreign Medical Review':—

"Towards the end of 1792, Pinel, after having many times urged the government to allow him to unchain the maniacs of the Bicêtre, but in vain, went himself to the authorities, and with much earnestness and warmth advocated the removal of this monstrous abuse. Couthon, a member of the commune, gave way to M. Pinel's arguments, and agreed to meet him at the Bicêtre. Couthon then interrogated those who were chained, but the abuse he received, and the confused sounds of cries, vociferations, and clanking of chains in the filthy and damp cells, made him recoil from Pinel's proposition. 'You may do what you will with them,' said he, 'but I fear you will become their victim.' Pinel instantly commenced his undertaking. There were about fifty whom he considered might without danger to the others be unchained, and he began by releasing twelve, with the sole precaution of having prepared the same number of strong waistcoats with long sleeves, which could be tied behind the back if necessary. The first man on whom the experiment was to be tried was an English captain, whose history no one knew, as he had been in chains forty years. He was thought to be one of the most furious among them; his keepers approached him with caution, as he had in a fit of fury killed one of

them on the spot with a blow from his manacles. He was chained more rigorously than any of the others. Pinel entered his cell unattended, and calmly said to him, 'Captain, I will order your chains to be taken off, and give you liberty to walk in the court, if you will promise me to behave well and injure no one.' 'Yes, I promise you,' said the maniac; 'but you are laughing at me: you are all too much afraid of me.' 'I have six men,' answered Pinel, 'ready to enforce my commands, if necessary. Believe me then, on my word, I will give you your liberty if you will put on this waistcoat.' He submitted to this willingly, without a word: his chains were removed, and the keepers retired, leaving the door of the cell open. He raised himself many times from the seat, but fell again on it, for he had been in a sitting posture so long that he had lost the use of his legs; in a quarter of an hour he succeeded in maintaining his balance, and with tottering steps came to the door of his dark cell. His first look was at the sky, and he cried out enthusiastically, 'How beautiful!' During the rest of the day he was constantly in motion, walking up and down the staircases, and uttering exclamations of delight. In the evening he returned of his own accord into his cell, where a better bed than he had been accustomed to had been prepared for him, and he slept tranquilly. During the two succeeding years which he spent in the Bicêtre, he had no return of his previous paroxysms, but even rendered himself useful by exercising a kind of authority over the insane patients, whom he ruled in his own fashion." Other instances are given of the efficacy of the mild treatment, which are not necessary now to be repeated to show its salutary effects.

If experience did not always prove that improvements of any kind are slow, and invariably met by opposition, we should be at a loss to account for the fact that in England, twenty-three years after the liberation of the lunatics at Bicêtre, a state of things equally bad, if not worse, generally existed. From the evidence given before the parliamentary committees in 1815, we gather facts, supported by the evidence of the attendants themselves, almost too horrible to be credible. Every artifice of cruelty seems to have been employed upon those who were already the most unhappy of mankind. The idea seemed to prevail that all the feelings of humanity were extinguished by the visitation of insanity. The keepers were, in all the English madhouses, of the lowest and most brutal character, merely distinguished by their success in controlling the violence of their patients by still greater violence, and by possessing the power of punishment. The account of the inquiry into the management of the York Asylum in 1813, written by the late respected Mr. Gray, gives probably a true picture of the state of the condition of the insane in general. This asylum was opened in 1777, and bore a fair character for organisation and management. Upon the establishment of the Retreat, at York, in 1796, a more humane system than had hitherto been known in England was introduced into its management; and in the description of it by the founder, Mr. Tuke, published in 1813, a recommendation of the milder mode of treatment was given. This was considered, and with some reason, to be an attack upon the management of the York Asylum; and it was followed up by a series of charges brought by Mr. Godfrey Higgins against this latter institution. The horrors ultimately made known would be beyond belief, were they not amply attested. Though the committee of the York Asylum long refused to listen to the charges brought by Mr. Higgins, they could not entirely conceal the facts; and the extent to which frauds of all kinds were carried by the steward assisted much in developing the general state of the house. A committee of inquiry was appointed; and on the day after their deliberations ceased (28th December, 1813), one wing of the asylum was destroyed by fire. How many patients perished is unknown; but at least four were missing. The steward entered four patients who were missing as "died;" but it is probable that there were many more. The real number in the house was probably unknown; for either by negligence or design the books had been so irregularly kept that the number of deaths to July, 1813, actually 365, was entered as 221, and 101 of those dead had been calculated among the cures. The committee refused to adopt the only method of ascertaining the number missing by requiring from each keeper an account of the patients under his care, from a pretended delicate objection to the divulging of the names of the inmates.

Mr. Higgins thus sums up the state of the management of the house:—"In the asylum investigations, concealment appears at every step of our progress; 365 have died: the number advertised is 221. A patient disappears, and is never more heard of, and is said to be 'removed.' A patient is killed—his body is hurried away to prevent an inquest. He is cured, but it is by some medicine the composition of which is known only to the doctor. The public cry out that a patient has been neglected; there is a levy *en masse* of respectable governors to quell the disturbance, and to certify that the patient has been treated with *all possible care, attention, and humanity*. A committee of investigation desires to be shown the house: certain cells 'in an extreme state of filth and neglect' are omitted to be pointed out to them. The governors examine the accounts: there are considerable sums of which neither the receipt nor the application appears. They inspect the physician's report: it only aids the concealment. The steward's books are inquired for: in a moment of irritation he selects for the flames such of them as he thought it not advisable to produce. And yet every circumstance of concealment is imputed by some to mere

accident; and every attempt to tear off the mask, and exhibit the asylum in its true character, is stigmatised as a libel or an indelicate disclosure!"

The details which were brought before the committee to exhibit the brutality and profligacy of the keepers need not be repeated; but it is gratifying to find that Mr. Higgins persevered, notwithstanding all the obloquy heaped upon him, until a complete change of the officers and of the system was brought about.

The next asylum of which we shall have occasion to notice the mismanagement is Bethlem, concerning which we find many particulars in the evidence given before the parliamentary committee in 1815.

The severest restraint and the most cruel neglect seem to have been the almost uniform practice; and it must not be forgotten that this royal hospital, favoured with exemption from all visitation and from the effects of acts of parliament, has been, until a recent period, the most determined in resisting the abolition of restraint, in preserving ancient abuses, and in closing its doors against inspection. With such large funds at command, Bethlem ought to be a model where the student of medicine may see every late improvement in the treatment of mental disorder carried into effect, without regard to the economy which has been detrimental to the improvement of many other asylums. And Bethlem now (1860) does indeed boast of being the most advanced in the system of non-restraint: public balls and other amusements being allowed to the patients.

In 1815 Bethlem appeared to have been going back, rather than improving, for half a century. From the time that the indiscriminate visits of the public had been prohibited, the secrets of the institution were known only to a few. The case of Norris, a patient in Bethlem, which was made public by the parliamentary committee, has often been related; but it will not be out of place here. William Norris had been an officer in the navy, and was first confined at Bethlem in 1801. In 1803 he is said to have struck Mr. Haslam, the apothecary; and whether from any real fear of him or as a punishment, a new and most ingenious instrument of torture was invented for his confinement. "A stout iron ring was riveted round his neck, from which a short chain passed to a ring made to slide upwards or downwards on an upright massive iron bar, more than six feet high, inserted into the wall. Round his body a strong iron bar, about two inches wide, was riveted; on each side of the bar was a circular projection, which being fashioned to and inclosing each of his arms, pinioned them close to his sides. The waist bar was secured by two similar bars, which, passing over his shoulders, were riveted to the waist bar both before and behind. The iron ring round his neck was connected to his shoulders by a double link. From each of these bars another chain passed to the ring on the upright iron bar. His right leg was chained to the trough, in which he had remained thus encaged and enchained twelve years. He read books of all kinds, and reasoned quite coherently on the events of the war." During the whole of this period it was impossible for him, from the nature of the restraint in which he was placed, either to stand quite upright or to lie down at ease. It will be no matter of surprise that he died on the 26th of February, 1815.

From this time a gradual but very slow improvement in the condition of the insane may be observed. Chains were removed, and leathern restraints of much milder kinds substituted; and more care was given to the warming and clothing of the patients. Some of the largest asylums in England were opened between 1815 and 1825. The introduction of employment by Sir William Ellis at Wakefield, and afterwards at Hanwell, was a great advance in the amount of confidence reposed in patients; employment has since been introduced in almost every asylum, and no serious accident, so far as we are aware, has ever occurred from allowing the use of tools. The credit of declaring the total abolition of mechanical instruments of restraint to be desirable and practicable, belongs to Dr. Charlesworth and Mr. Hill, of the Lincoln lunatic asylum. The progress of the alteration was given by Mr. Hill in a lecture delivered by him at the Lincoln Mechanics' Institution, 21st June, 1838, and afterwards published with the addition of extracts from the 'Proceedings' of the asylum, and tables showing the gradual disuse of restraint. A reference to a few of these will illustrate this part of the history of the non-restraint system. The Lincoln asylum was opened on the 26th April, 1820, and was conducted from the first on humane principles, but with all the usual instruments of restraint.

On the 29th February, 1829, it is reported that a patient has died in the night in consequence of being strapped to the bed in a strait-waistcoat, and an order is consequently given that the use of the strait-waistcoat shall be discontinued, except under the special written order of the physician; and also that every case of restraint shall be entered in a journal, with its nature and duration.

On the 4th May, in the same year, the "heaviest pair of iron hobbles," which were jointed, and weighed 3 lbs. 8 oz., and the "heaviest pair of iron handcuffs," which weighed 1 lb. 5 oz., are ordered to be destroyed; five strait-waistcoats are likewise condemned.

Numerous entries in 1829, 1830, 1831, and 1832 prove the diminished use of coercion. On the 16th July, 1832, is the first order for strong dresses for such patients as tear their clothes. These patients were in all asylums the most subject to continual restraint.

21st July, 1834. All the instruments which would confine the fingers were ordered to be destroyed; but manacles for the wrists and

leg-locks were retained. March, 1837, the system of restraint was entirely abolished.

Mr. Hill's lecture, which contains much that is exceedingly interesting upon this subject, has the following sentence, which has been the text on which all the controversy on the abolition of restraint has been founded:—"In a properly constructed building, with a sufficient number of suitable attendants, restraint is never necessary, never justifiable, and always injurious, in all cases of lunacy whatever." This sentence, when published in 1838, was declared even by those most inclined to the new system to be too decided, and likely to produce a bad effect; but fortunately the lapse of twenty years has proved its perfect truth, by its adoption as a principle in all the most important asylums in the kingdom. But the upholders of the old system received the announcement of a doctrine so startling as if there were something atrocious in proposing to liberate those who were unfortunate enough to be insane; and for years after restraint had been actually abolished, the non-restraint system was declared "utopian" and impracticable; then declared to be practicable, but not desirable; and at length, when every other argument failed, those who so strenuously opposed it came forward and claimed it as their own system, which they had been practising for years, excepting that it had been carried a little further.

The next asylum in which restraint was abolished was that of the county of Middlesex at Hanwell. At the time of the appointment of Dr. Conolly to the superintendence of the Hanwell Asylum (June, 1839) it contained eight hundred patients; of these about forty were almost constantly in restraint-chairs, and a number of others wore strait-waistcoats, muffs, leg-locks, &c. In addition to these restraints, which were supposed necessary for the safety of the rest and of the officers and attendants, more than a hundred epileptic patients were fastened by one wrist in bed every night. This was considered a necessary precaution to prevent the patients from falling out of bed or from turning on their faces in a fit, and so becoming smothered, which, it is asserted, has sometimes happened. No such cases however have occurred since the disuse of the hand-strap, which took place in July, 1839.

We extract from Dr. Conolly's first report (October, 1839) the following account of the discontinuance of restraint at Hanwell:—

"The article of treatment in which the resident physician has thought it expedient to depart the most widely from the previous practice of the asylum has been that which relates to the personal coercion or forcible restraint of the refractory patients. Without any intention of derogating from the high character acquired by the asylum, it appeared to him that the advantage resulting from the degree of restraint permitted and customary in it at the period of his appointment was in no respect proportionable to the frequency of its application; that the objections to the restraint actually employed were very serious; and that it was in fact creative of many outrages and disorders, to repress which its application was commonly deemed indispensable, and consequently directly opposed to the chief design of all treatment, the cure of the disease."

"By a list of restraints appended to this report, it will be seen that the daily number in restraint was in July so reduced that there were sometimes only four, and never more than fourteen, in restraint at one time; but that since the middle of August there has not been one patient in restraint on the female side of the house, and since the 21st of September not one on either side." The 51st report of the visiting justices, which accompanies this report, speaks of the new system as requiring an additional number of attendants, and of a superior class to those previously employed.

In their 52nd report (January, 1840) the visiting justices report the satisfactory results of the new system. In the 53rd (April, 1840) they report that "there has not been a single occurrence to weaken their confidence in the practicable nature of the system;" and also "that no increased destruction of clothing or other property is occasioned by the personal freedom which the patients enjoy. Indeed, so far as clothing is concerned, the amount of destruction is somewhat lessened, because of the general tranquillity of the patients from the adoption of the new system."

Dr. Conolly, in 1844, also says: "After five years' experience, I have no hesitation in recording my opinion, that with a well-constituted governing body, animated by philanthropy, directed by intelligence, and acting by means of proper officers, intrusted with a due degree of authority over attendants properly selected and capable of exercising an efficient superintendence over the patients, there is no asylum in the world in which all mechanical restraints may not be abolished, not only with safety, but with incalculable advantage."

Here we may consider the subject of non-restraint concluded so far as its practicability is concerned. It is nowhere insisted that restraint can never be necessary in ill-conducted asylums, and until houses for private patients are constructed for the purpose for which they are used, some restraint will probably be used in many of them.

In the article LUNACY we have given notices of the various legislative acts for the management of Lunatic Asylums, and the appointment of commissioners, who are bound to examine frequently, and to report annually on the state of every public or registered asylum for the care of the insane. From their last report, the thirteenth, for the year

ending December 31, 1858, it appears that there are 44 county and borough asylums now in England (2 of them, Cumberland and Glamorgan, not yet (1860) open). The only large town not possessing one is the city of London, notwithstanding the repeated remonstrances of the commissioners; but one is about to be erected at last at Dartford. There are 38 metropolitan and 74 provincial licensed houses; with 15 hospitals which receive lunatics, including the one at Earlswood for idiots only. The following is the summary as given in the Commissioners' Report for the year ending December 31, 1858:—

COUNTY.	Number of Patients.	In County or Borough Asylums.	In Registered Hospitals or Licensed Houses.	In Workhouses.	In Lodgings, or Boarded out.	Residing with Relatives.

Grand total	29,858	14,553	2097	7642	1112	4454

In the year there had been 8146 admissions; and 4942 discharges, of which 3079 were recoveries, of which 1399 were males and 1680 females. Of the patients remaining, 2779 were deemed curable. There had been 2306 deaths, of which 1274 were of males, and 1032 females: 7 females and 5 males had committed suicide.

The report of the commissioners on their visitations was on the whole favourable. The chief complaint was the want of space for exercising grounds; the neglect of providing night assistants, which the commissioners strongly urge, as the best means of counteracting

* Patients chargeable to counties and boroughs, and also certain criminal patients, are not included in the above totals.

the habits of dirty patients and for the prevention of accidents; and the insufficiency of the pay to secure able and trustworthy assistants. On the whole, they find that the system of personal restraint has been nearly altogether abandoned, and that of solitary confinement greatly, but not as they think sufficiently lessened. Their efforts, however, have not been altogether effectual. Some remnants of the old system remain, in spite of their remonstrances, in the private asylums. They thus describe one:—"The premises present a cheerless aspect. Many of the rooms have no windows, and are entirely dark. Some are lined with sheet-iron. The windows are guarded with heavy iron bars, and those, with the iron gates and railings, give the place a most jail-like appearance. Some of the sitting-rooms are without furniture, except fixed forms, and boards against the walls for tables. In these the floors are flagged, and the windows placed high up near the ceiling. There are out-buildings, where the patients are placed without attendants, and where no means for warming exist. The airing-court walls are high, and obstruct the view of the surrounding country." This is the state after some improvements had been made, and after repeated remonstrances.

Of the Asylum for Idiots at Earlswood, the reports published by the directors speak most favourably, though that of the Lunacy Commissioners is not altogether so commendatory. It recommends more attention to the improvement of the physical condition of the patients, with more of out-of-door exercise, thus developing their feeble intellect, with less pressure upon it by scholastic tuition; adding, in a report of February 23, 1859, that these recommendations have been adopted, and that its present management reflects credit upon the officials. At that date there were upon the premises 279 pupils, 187 of whom were males, and 92 females. The institution has been remarkably successful in developing the intellect, so as to make the patients at least useful and well ordered, in humble branches of industry, consequently more happy themselves, and a less burden to their friends and families.

In Scotland, the custody of the insane was, like every other matter which demands both magisterial and executive intervention, connected with the system of local courts. The law on the subject is now embodied in the 20 & 21 Vict. c. 71, as amended by the 21 & 22 Vict. c. 89, and the system of management of the insane in Scotland has, both in a purely medical and in an administrative point of view, been vastly improved. Until a comparatively late period the statute law was nearly inoperative, from a strong prejudice against the enforcement of general rules relating to the treatment of the insane, and the consequent toleration for breaches of the statutory regulations. The rule adopted in practice was, that insane persons were allowed to go at large until they had proved themselves dangerous to the lives of their neighbours, and that when confinement was in any case resorted to, the proceedings were not very rigidly investigated. There are now 8 public asylums, 24 private asylums, and 27 poorhouses, in which lunatics are maintained, and there are 1784 paupers kept in private houses. The total number of lunatics at the end of 1858, was 5748, of whom 2718 were males, and 3030 females; of this total 4737 were paupers. In the year, 188 males and 182 females had died. There had been 244 males and 379 females discharged recovered, and 198 males and 216 females not recovered. The admissions in the year were, 705 males and 921 females. In 1859, the number had been a little over 5000, of whom 392 died, and 497 were cured. The proportion of cures to deaths had been improving every year since 1856.

In Ireland, two inspectors of lunatic asylums, with the requisite assistants, have been appointed; and the erection of county lunatic asylums has been zealously carried forward. There are now 16 district asylums in operation, several of them being for the reception of patients from two or more counties which have associated themselves for that purpose; and a central one at Dundrum, county of Dublin. Between 1855 and 1860, there was expended on the construction of such asylums the sum of 356,114*l*. The ninth report of the inspectors of Irish lunatic asylums, gives the total number of the insane of all kinds on March 31, 1859, as 11,218, of this number (at the end of 1857), 4262 were at large, there not being sufficient accommodation for them in asylums at that time; the number being no doubt greatly reduced in the interval. Of the remainder, 2087 males and 2003 females were in the district asylums; 89 males and 41 females were in the central asylums; in jails, 116 males and 107 females; in poorhouses (April 2, 1859), 722 males and 1324 females; and in private asylums (December 31, 1858), 254 males and 213 females; giving a total of 3268 males and 3688 females under care and supervision. There are, in addition, 44 women and 30 men in the Dublin Hospital for Incurables. The general management, treatment of the patients, and construction of the buildings, are similar to those adopted in Great Britain, modified in some unimportant details by peculiar circumstances.

So many public asylums having been built, there has been a great variety of construction. The chief requisites insisted on by the commissioners, are light, ventilation, proper means of warming, convenience and cheerfulness in the furniture, and, above all, ample means for out-door exercise. The only doubtful part of the arrangement is the dormitories, some good authorities preferring open wards, as admitting the most effective superintendence at night; others advocating separate sleeping apartments, as being less likely to admit of any

one patient disturbing another. Both plans have been adopted; and the results do not appear to differ materially.

A great improvement has taken place in the class of persons appointed as attendants, or, according to the old phraseology, *keepers*. That all such persons should possess benevolence and intelligence is essential to the effective working of a humane and enlightened system; and they should be liberally paid. The proportion of attendants to patients in the different English public asylums varies from one to ten, to one to twenty; the former does not seem too much, and is far less than that in all well-managed private asylums. No ward, however small, should have less than two attendants, in order that it should never be left without one; this is enforced by the rules of several asylums; and is most essential wherever a night attendance is adopted. In some asylums this attendance is endeavoured to be effected by making the day attendants undertake night duty in turns; but this is taxing their physical powers too severely, even when they are released from duty for half the succeeding day.

LUNATION, the time between two new moons. [MOON.]

LUNE, LUNULE, the figure formed on a sphere or on a plane by two arcs of circles which inclose a space. [HYPOTHENUSE; SPHERE.]

LUNETTE, in fortification, is a work similar to a ravelin, or demi-lune, but generally of smaller dimensions. Such works have been placed in the retired angles between the ditches of a bastion and of the collateral ravelin, but they are now usually considered as advanced works, and are placed in front of those just mentioned.

The form of a lunette is the same as that of the redoubt *Y* in the plan at the end of the article FORTIFICATION; and its positions may be understood by conceiving such works to be placed beyond the glacis *SS* on lines passing through *P* and *Z*, *X* and *R*, and produced. Each lunette is protected in front by a ditch beyond which is a covered-way, as usual.

The best disposition for a series of such works is that in which they are alternately more and less advanced beyond the fortress; since then they afford one another a reciprocal defence by the crossing fires which may be kept up from the nearest faces of every salient and retired lunette. And should the besiegers succeed in carrying their approaches up the glacis of the latter, the artillery on the flanks of the two more salient and collateral lunettes would effectually prevent them from forming a battery on its crest to breach the work. The operations against any one retired lunette must consequently be postponed till the two collateral lunettes are taken; whereas had all been equally advanced beyond the fortress, the three might have been breached and assaulted at the same time.

To give the more advanced lunettes, which are generally those placed beyond the ravelins, all the advantages of which they are susceptible, the magistral lines of their faces should coincide with the sides of an equilateral triangle whose base is a line joining the faces of the two collateral bastions at points about twenty or thirty yards from their flanked angles; for thus the earthen parapets at the salient angles of the lunette will not be easily destroyed by rain, and the ditches before the faces of the work can be defended by two or more pieces of artillery conveniently placed on the faces of the bastions. The ditches of the retired lunettes should in like manner be defended by artillery placed on the faces of the collateral ravelins; and the magistral lines of their faces should consequently be directed towards such ravelins.

In a front of fortification of the ordinary extent (360 yards) this rule for placing the advanced lunette, will permit the ditch and covered-way of the latter to be defended by a fire of musketry from the retired places of arms *LL* [FORTIFICATION], and from the covered-way before the bastions; and, that such fire may graze the bottom of the ditch of the lunette, this ditch ought to be in an inclined plane nearly coinciding with the slope of the glacis *SS*. Should the ditch so formed be too shallow to fulfil its end, which is that of being an obstacle to the enemy in his attempt to assault the lunette, it would be necessary to make it deeper; and that it might not thus become a trench in which the enemy would be covered from the fire of the defenders, it should communicate with water, by which it might be filled previously to the expected assault.

The rampart of a lunette differs in no respect from that of other works; it should have the same relief, or height above the natural ground, as is given to the ravelins; since, as in the latter work, the fire of artillery should be capable of being directed against the trenches of the enemy at the foot of the glacis, over the heads of the defenders on the banquette of the covered-way. Its escarp should be revêted with brick or stone, in order that the enemy may be compelled to form a breach in it by artillery, or by a mine, previously to making an assault; or at least that the attack by escalade might be a process of difficulty and danger. The terreplein, or ground in the interior, should be high enough at the gorge to prevent an enemy from entering there without scaling-ladders; this part should be further protected by a loop-holed wall, or a line of palisades; it should be seen and defended from some collateral work, and an open caponnière, or a subterranean gallery, for communication, should lead from the gorge of each lunette to the place of arms in its rear. The advanced covered-way should pass in front of all the lunettes, and it might terminate at the two extremities on inaccessible ground, or in the general covered-way of the place.

Advanced lunettes about a fortress form strong posts for artillery, by which an enemy is compelled to commence his approaches at a

greater distance than would otherwise be necessary. The length of their faces may be from sixty to seventy yards, and that of their flanks from fifteen to twenty. It is considered that a well-disposed series of these works would prolong the defence of a place about ten or twelve days. But they are only proper for fortresses of the first magnitude, since they would require a large garrison; and the troops on being compelled to retire, might not find sufficient room in a small place.

LUNGS, DISEASES OF THE. The highly organised structure of the lungs and the incessant exercise of their important function, frequently under noxious circumstances, render these organs perhaps the most liable to disease of any in the body. Exposure to damp and cold, sudden atmospherical changes and transitions of temperature, want of proper nourishment, inattention to personal cleanliness, and some of the mechanical employments in which the confined and heated atmosphere of workshops is impregnated with minute particles of foreign substances, such as steel, wool, &c., may be considered as amongst the chief exciting causes of this extensively prevailing class of diseases. The subject may be conveniently divided into those affections which are acute and rapid in their progress, and those in which their course is slower and the changes of structure more gradually effected.

In *inflammation of the lungs* (pneumonia peripneumonia) the air-cells and parenchymatous structure of the organ are the seat of the disease. This affection is generally preceded in a greater or less degree by shivering and such other febrile symptoms as commonly usher in any febrile attack. Soon afterwards pain and a sense of oppression are felt in the chest, with hurried respiration and a short dry cough. The pain is sometimes severe, sometimes it is described as of a dull and obscure kind and deeply seated. If the pleura, or investing membrane of the lungs, participate in the affection, it is generally severe. At first there is little expectoration, but this increases in the progress of the disease, and the sputa acquire a reddish or rusty colour from the admixture of small quantities of blood. They also possess an unusual viscosity and tenacity, sometimes to such a degree that the vessel into which they are received may be inverted without their falling out; they also contain numerous minute bubbles of air, which are prevented from escaping by the consistence of the secretion.

If the disease continue unchecked, the difficulty of breathing becomes much greater, and the respirations, which in the natural state are about 20 in a minute, increase in frequency to about 40 or 60. Sometimes there is little cough throughout the disease, but most commonly it increases as the disease advances, and the sputa become more deeply tinged with blood. The features subsequently assume a livid appearance; the breathing gets more oppressed; expectoration is effected with difficulty; the powers of life fail, and the patient dies from the lungs being no longer able to carry on their function.

When a favourable change takes place in the course of the disease, either spontaneously, or from judicious medical treatment, it is generally attended by perspiration, the expectoration loses its rusty colour and unusual tenacity, the urine becomes turbid, and sometimes there is diarrhoea. Andral and other authors are of opinion that improvement is most likely to take place at certain times—critical days. The diagnosis of this disease has received most important assistance from auscultation, and in many instances it has been detected by its aid, where formerly it would have been overlooked. The assistance afforded by the auscultatory signs will perhaps be better understood if we defer them until we have spoken of the changes of structure in the lungs occasioned by inflammation.

In the early stage of pneumonia the inflamed part acquires an unnatural density and heaviness from the unusual accumulation of blood in it, and if a portion of lung so circumstanced be examined after death, pressure with the finger on its surface leaves an indentation which is not filled up, as would immediately be the case in a healthy state of the part. When it is cut into, a bloody frothy fluid exudes freely from it, and the surfaces present a deep blood-red colour, and if a portion be squeezed between the finger and thumb a crackling noise is heard indicating the presence of air. In a more advanced state, the lung is found still more dense, and does not crepitate when squeezed, showing that air is no longer admitted. As in this condition it somewhat resembles liver, it has been termed the stage of *hepatisation*. When the disease has proceeded still further, suppuration may be found to have taken place. Pus is then observed to be effused throughout the structure of the diseased part, by which its dull red is changed to a yellow or straw colour, and the mass is rendered soft and easily broken. Suppuration in the form of abscess very rarely occurs as a consequence of pneumonia. Laennec is of opinion that death most probably takes place before the change can have proceeded to that extent.

Auscultatory Signs.—In that stage of the disease in which there is only an accumulation of blood in the part, and whilst air is still admitted, the respiratory murmur is heard on examining the chest with the ear or stethoscope, but it is attended with a crackling sound which resembles that produced by rubbing a portion of hair between the finger and thumb near the ear, or by throwing salt into the fire; this is commonly called crepitous rattle or rhonchus, crepitous respiration or *crepitation*. A clear sound is also heard on percussing the chest.

If the disease has proceeded to the stage of hepatisation, the lung

being in that part solid and impervious to air, percussion will afford only a dull sound without resonance, and the murmur attendant on respiration will be altogether wanting. Should a large bronchial tube pass near the hepatized portion, the resonance of the voice in the bronchus will be heard more distinctly than usual, on account of the solid being a better conductor of sound than the healthy lung.

When suppuration has taken place, the sound on percussion is also dull, and the natural respiratory murmur is wanting, but in its stead a loud gurgling noise is heard, resembling that produced by air passing through soap-suds, called *mucous rhonchus*. It is perhaps occasioned by pus escaping into the larger air-tubes.

Treatment.—The treatment of inflammation of the lungs must be conducted on the same general principles as inflammation occurring in any other part. The question of bleeding for the inflammation in this disease must be decided on general principles. Many practitioners avoid bleeding in this and other inflammations, unless the symptoms of dyspnoea become urgent from an embarrassment of the circulating organs. Even here the question arises, as to whether by weakening the system by bleeding, the congestion of the lungs may not be increased. At any rate all are agreed that having recourse to bleeding in all stages of this disease, is frequently a dangerous practice. The practice most generally adopted in this country is the administration of small doses of tartarised antimony and calomel every three or four hours. Leeches and cupping to the chest, with blisters, have also been found beneficial. The bowels, skin, and kidneys, should be acted on by purgatives, diaphoretics, and diuretics.

Inflammation is sometimes confined to the bronchial tubes, and is called bronchitis; it may also co-exist with pneumonia. [BRONCHITIS.]

Mortification or gangrene of the lungs, though sometimes occurring as a result of pneumonia, most frequently takes place as an independent affection. It is often connected with the tuberculous condition of the lungs. Great fetor of the breath, with an expectoration of dark-brown, greenish, and fetid sputa, excessive debility, and a cadaverous expression of countenance, are the symptoms by which it is indicated. After death portions of lung are found in a partially decomposed state, of a dark brown or dirty greenish appearance, with a putrid smell. Occasionally, under favourable circumstances, the mortified parts have been separated and removed by expectoration, and the patients restored to health; but this is not a result which can commonly be looked for. The disease has been known to occur sometimes as a consequence of working in cesspools, and of long exposure to the noxious effluvia attendant upon such occupations.

Hæmoptysis; Spitting of Blood.—Expectoration of blood may occur either by exhalation from the mucous membrane of the air-tubes or from the lesion of a blood-vessel. It generally occurs in early life, from the age of fifteen to thirty-five, and in the former instance may be dependent upon local congestion. This determination of blood to the lungs may be occasioned by the sudden suppression of some natural or accidental discharge from other parts, as in suppressed or impaired menstruation, or the arrest of an hæmorrhoidal discharge. Malformation of the chest also, by interfering with the free circulation through the lungs, or an impeded transmission of blood through the abdominal viscera, from the presence of tumours or ascites, may likewise contribute to produce it. Sometimes it appears to be dependent upon an altered condition of the blood itself, as in purpura and some eruptive fevers; but its most frequent cause is tubercular disease of the lungs, in which it may arise in an early stage from the obstruction to the circulation occasioned by the tubercles, or subsequently from the vessels participating in the ulcerative destruction. An attack of hæmoptysis should lead to an accurate examination of the chest, in order to ascertain whether tubercles exist.

A remarkable sympathy has been observed to exist between the uterus and the organs of respiration, and spitting of blood has sometimes been known to precede the appearance of the menses, and to cease entirely on their accession. Sometimes it has been found to supersede the discharge altogether, or to make up for a deficiency in its quantity.

An attack of hæmoptysis is usually preceded by certain premonitory symptoms, such as chilliness, headache, lassitude, and a quick and vibrating pulse. The patient also experiences a sensation of weight and constriction at the chest, with a feeling of heat and itching in it. The expectoration of blood is attended with cough. Sometimes the quantity brought up is very considerable, and is expelled with violence; at other times the sputa are only streaked with it. The expectorated blood is generally of a vermilion colour, and when in small quantities, it is frothy and mixed with air. When the blood comes from the stomach, it is brought up by vomiting and without cough, without the frothy appearance, and is of a dark grumous character.

Pulmonary Apoplexy.—When it happens that the blood, instead of being exhaled into the air-tubes, is effused into the parenchymatous structure of the lungs, the name of pulmonary apoplexy is given to it. One or two lobules, or a small portion of the lungs only, may be affected in this manner, the structure of the part not being broken down by it. When this is the case, hæmoptysis may not take place. Such effusions are found after death in the form of circumscribed indurated masses of a dark brown colour nearly approaching to black, and surrounded by the lung in a perfectly healthy state. Life not being immediately destroyed in such cases, time is given for the

absorption of the most fluid parts of the blood, which will account for the indurated character of these deposits. When the effusion is more extensive, large portions of the substance of the lung may be torn and broken down, and hæmoptysis to a very considerable and generally immediately fatal extent takes place.

One of the most common causes of pulmonary apoplexy is disease of the heart, by which the circulation through the lungs is impeded and oppressed with blood. The causes mentioned as conducing to hæmoptysis are also common to this affection, and the symptoms are very similar. The plan of treatment in these affections is founded on the same general principles as are applicable in any case of internal hæmorrhage. [HÆMORRHAGE.]

Phthisis Pulmonalis is by far the most frequent and most fatal of all diseases of the chest. [PHTHISIS PULMONALIS.]

Malignant Diseases of Lungs.—The lungs are also subject to diseases of a specifically malignant nature, such as medullary sarcoma and melanosis; but these rarely occur as a primary affection. The medullary and melanoid matter is deposited in these organs as a secondary affection, in conjunction with its existence in other parts, and frequently in all or the majority of the organs of the body.

Black or Carbonaceous Matter in the Lungs.—A peculiar discoloration in the lungs of persons who have died after working for a long period of time in coal-mines, or in mines where gunpowder is used in large quantities for blasting masses of rock, has been observed. The lung is found of a coal-black colour throughout, though still perfectly natural in all its other characters. It also exists in connection with disease of the lung, and the expectoration of persons so affected partakes of the same colour. The cause of it seems to be doubtful; but most probably it arises from the inhalation and absorption of the carbonaceous matter existing in the atmosphere of such mines.

Bony and cartilaginous tumours have been found in the lungs, and the membrane surrounding the lungs (the pleura) is sometimes met with converted into bone; sometimes it is studded with tubercles similar to those found in the lungs of Phthisis.

For an account of inflammation of the pleura see PLEURISY.

LUPININ, a bitter non-azotised matter of unknown composition contained in lupin seed.

LUPULIN. [HOPS; HUMULUS, in NAT. HIST. DIV.]

LUPUS (the Wolf), one of the old constellations, named in Aratus and Ptolemy simply *Θήριον*, "the wild beast." It was not a separate constellation, but was carried in the right hand of the Centaur towards the Altar. The same description is given by Hyginus. In modern maps it is represented as a wolf transfixed by the spear of the Centaur. It is situated between Centaurus and Ara, directly under Scorpius.

LUSTRUM was the name applied to a period of five solar years among the Romans, and the termination of this period was generally marked by great religious solemnities. A purifying sacrifice, called *suovetaurilia*, was usually offered at this time by one of the censors in the Campus Martius (Liv., i. 44); and the victims consisted of a cow, a sheep, and a bull, which were led round the people three times and then slain; but this sacrifice was sometimes omitted on religious grounds. (Liv., iii. 22.) The first of these services was solemnised at Rome under King Servius, B.C. 566; the last under Vespasian, in A.D. 74. Varro ('De Ling. Lat., v. 2) derives the word *lustrum* from *luere*, because the farmers paid their taxes at that time; but others, with more probability, trace the etymology to the purifying sacrifice which was then offered.

It is well known that the most ancient Roman year consisted only of 10 months, or 304 days, and that this year continued to be used for religious purposes. Niebuhr, in his 'History of Rome,' has shown that the *lustrum* was the period after which the beginnings of the civil and religious years were made to coincide; since five solar or civil years of 365 days each, containing 1825 days, coincide with six religious years of 304 days each, containing 1824 days, with the difference of one day.

In the time of Domitian the name of *lustrum* was given to the public games which were exhibited every fifth year in honour of the Capitoline Jupiter. (Sueton., 'Domitian,' c. 4.) The poets frequently used the word for any space of five years (Hor., 'Od.,' ii. 4, 24; iv. 1-6), and sometimes confounded it with the Greek olympiad, which was only a space of four years. (Ovid, 'Pont.,' iv. 6-5; Martial, iv. 45.)

(Niebuhr's *History of Rome*, vol. i., pp. 270-280, Eng. transl.; Creuzer's *Abriss der Römischen Antiquitäten*, p. 146; and the article CENSOR in this work.)

LUTE, a musical stringed instrument with frets, one of the numerous varieties of the ancient cithara. Until towards the end of the 17th cen-

tury its practice formed an essential part of a good education, but it has since been partially superseded by the guitar: nevertheless, the salaried office of *lutenist* is still continued in the Chapel Royal, though the place is a sinecure. The derivation of the word is probably to be traced to the Teutonic *lut*, whence, modified, it has passed into all the European languages, whether cognate or otherwise. The German verb *lauten*, to sound, is derived from *laute*, a lute.

We do not meet with any notice of this instrument, so named, before the time of Dante, who, ludicrously enough, compares the swelled figure of a person suffering under dropsy to the form of the lute. The shape of the body and principal or lower neck may be seen in our wood-engraving of the ARCH-LUTE. Mersenne, in his 'Harmonie Universelle' (1636), describes the lute as consisting of three parts: the *table*, made of fir; the *body* or *belly*, of the same wood, or cedar, constructed of nine convex ribs joined; and the *neck*, on which was fixed the finger-board, of hard wood, having nine frets made of cat-gut. To these is to be added the *head* or *cross*, in which the pegs or screws were placed. Thomas Mace, a celebrated teacher of the lute, in a curious work entitled 'Musick's Monument' (1676), agrees in the description given by the learned French monk, adding a great number of other particulars relative to the construction and use of the instrument: to this remarkable folio we refer those who are desirous of minute information on the subject. We shall here only state, from the same writer, that the lute had at first six strings, or rather eleven, for the five largest were doubled; but that the number was gradually increased till it reached twenty-four. He tells us that in his time a very choice instrument fetched the sum of 100*l.*, which may be considered as equal to 400*l.* of our present money. [ARCH-LUTE; GUITAR.]

The notation for the lute, theorbo, &c., called the *tablature*, differed entirely from that of other instruments. "The chords," says Sir J. Hawkins, "are represented by a corresponding number of lines, and on these are marked the letters *a, b, c*, &c., which letters refer to the frets on the neck of the instrument. The time of the notes is signified by marks over the letters of a hooked form, that answer to the minim, crotchet, &c. This is the French tablature; but the Italians, and also the Spaniards, till of late years, made use of figures instead of letters." There were many kinds of tablature, but being now obsolete and forgotten it is unnecessary to add anything further concerning them.

LUTEOCOBALTIA. [COBALT, *Ammoniacal Compounds of*.]

LUTEOGALLIC ACID, a peculiar acid extracted from nut-galls by ether.

LUTEOLIN is a non-azotised colouring principle found in the woad (*Reseda luteola*). It is volatile and crystallisable.

LUTES, in chemistry, are substances employed in various operations for closing the joints of apparatus, and especially for connecting retorts and receivers, so as to prevent the escape either of the vapour or gases generated during distillation or sublimation. The term lute is also applied to the external coating of clay and sand, or other substances, applied to glass retorts, in order that they may support a high temperature without fusing or cracking. For operations on the large scale, as the distillation of aquafortis, hydrochloric acid, &c., common plastic clay is a sufficiently good lute. Sometimes it has been recommended to use what is termed *fat lute*, but this generally only in small distillations, as of nitric acid: this lute is prepared by mixing dried and powdered pipe-clay into a paste with linseed oil; and the joint is further secured, both where this lute is used and in many other cases, by tying it over with moistened bladder.

In most operations, however, a mixture of pipe-clay and meal, as linseed meal or almond powder, is quite sufficient, when secured by bladder, for any purposes, either when acids or ammonia are to be distilled. In luting common stills, in which oils or water are merely distilled, linseed meal and water, made into a paste, form an effectual lute.

In luting, or rather coating, glass retorts, in order to enable them to sustain high temperatures, Stourbridge clay or Windsor loam mixed with tow have been used; but they require long drying, and are apt to crack. The simplest mode is that of brushing the retort over with a paste of pipe-clay and water, sifting sand upon it, drying it quickly in the ash-pit of the sand-heat, then covering it again with clay and sand, and repeating the alternate applications and drying till the coating is judged sufficiently thick.

An excellent lute for these purposes consists of a mixture of Stourbridge clay and asbestos, made into a paste with water.

LUTIDINE (C₁₁H₉N), an alkaloid isomeric with *toluidine*, found in bone-oil, and also formed during the distillation of cinchonine. It is a volatile oily body, lighter than water, and forms very soluble salts with most of the acids.

LYDIAN MODE. [MODE.]

LYNX, a constellation of Hevelius, situated directly in front of Ursa Major, the head of the animal being half-way between α Ursa Majoris and Capella. Its principal stars are as follows:—

LYON KING-AT-ARMS. [HERALD.]

LYRA (the Harp), one of the old constellations, representing the lyre of Mercury (Aratus), or of Orpheus (Hyginus). It is surrounded by Cygnus, Aquila, Hercules, and the head of Draco. Its brightest star, α Lyrae, also called Vega, is a conspicuous object. If a line be drawn through the middle of Cassiopeia, the pole-star, and the middle of Ursa Major, this star may be seen nearly in the perpendicular to that line drawn through the pole-star. When Aquila is known, a line drawn through its four neighbouring stars, θ, β, α , and γ , will pass through α Lyrae. Its principal stars are as follows:—

LYRE ($\lambda\upsilon\alpha$), a musical instrument of the stringed kind, known, under various names, from the earliest historical period. The Greeks ascribe its invention, some to Hermes, some to Apollo; but it is possible that they may have had it from the Egyptians, and the Egyptians from Asia. Indeed Holy Writ leads us to conclude that it was of antediluvian origin. Jubal, the seventh only in descent from Adam, was "father of all such as handle the harp and organ;" and as by the word *harp* we are to understand either the *lyre* itself, or some instrument analogous to it, we must, on such authority, grant to the son of Lamech the merit of being its inventor. In our version of the Scripture, *kinnor* (כנור) is rendered by the word *harp*, while the Septuagint and Vulgate give the Hebrew term a Greek form—*κithara*, *cithara*, a word generally, though we believe erroneously, supposed to be synonymous with $\lambda\upsilon\alpha$, or lyre. Erroneously, we say, because it is our opinion that lyre and cithara (or guitar) were generic terms; the first being the parent of all instruments of the harp kind, having no neck or finger-board; the last, of all those furnished with a neck, and which finger-board probably was divided by frets. [GUITAR; HARP.]

Fig. 1.

It is true that in all the remains of Grecian art, no instrument with a neck is to be found. Artists perhaps preferred the more compact and elegant form of what is now called the Grecian lyre. The same taste descended to the moderns; witness the statue of Handel formerly in Vauxhall Gardens, as Dr. Burney well remarks. Montfaucon tells us that he had examined the sculptured representations of six hundred ancient lyres and citharas, and found not one with a neck. But had the learned father—who was a most excellent and indefatigable antiquary—lived in the present day, he would have met with abundant evidence in Egypt to prove that instruments with necks—instruments

Fig. 2.

of the guitar kind, such as were subsequently called *lutes*—existed at least three thousand years ago. The three-stringed guitar, says Sir J. G. Wilkinson ('Manners and Customs of the Ancient Egyptians'), was in use at the earliest period of the Egyptian history; "those at the Pyramids are apparently of a date long previous to Osrtasen, or the

arrival of Joseph." And in Rosellini's splendid work 'I Monumenti dell'Egitto e della Nubia' are many engravings, some coloured, exhibiting instruments of great antiquity, resembling in essential points the modern guitar, or lute, with a neck, but this much elongated.

The most ancient Grecian lyre—said to have been formed by Hermes from the shell of a tortoise, and of which the annexed is a representation, as given by Mersenne, had but three strings (*fig. 1*). That of Terpander (from Blanchinus) had seven, and took the form given in *fig. 2*.

Timotheus increased the number to eleven; and others were gradually added, till they reached sixteen, fifteen of which rendered the principal sounds in the Greek scale, and the sixteenth was the *Proslambanomenos*, that is, the added or supernumerary sound.

LYRIC POETRY is commonly understood to be that kind of poetry which is composed in order to musical recitation, but the epithet has been transferred to all kinds of verse partaking in any degree of the same nature as that to which it was at first applied. Thus we hear of lyrical ballads, the greater part of which might with as great propriety be called epical, and of lyric measures in Horace, where there is no ground to suppose that they were sung, and no fitness for the purpose of musical rehearsal. In a former article [EPIC POETRY] we have endeavoured to point out a distinction between epic and lyric poetry more satisfactory than common language allows; but there is surely no impropriety in giving a decided meaning to words which have usually been understood in a confused sense, particularly when, as in the present case, the same senses have been applied to each, so as not only to confuse, but to confound them. Pursuing then the course which we have pointed out, lyric poetry must be defined as that class of poetry which has reference to and is engaged in delineating the composer's own thoughts and feelings, in distinction from epic poetry, which details external circumstances and events.

The history of lyrical poetry is perhaps subject to greater difficulties than any other species of composition. In that nation where it attained to its most perfect growth, it is precisely that class of its literature which is to us, except in regard to one author, a total blank. Pindar is nearly all that remains to us of the whole lyric poetry of Greece, and great as his reputation has deservedly been, we have no reason to consider him as paramount to his class, and very good reason for depecting to him what has commonly been considered his right, that of presenting us with the purest type and example of a lyric poet. And scarcely any trace remains of that link between epic and lyric poetry which was the origin of Greek tragedy. This was perhaps the most national form of lyric poetry among the Greeks, the others having been for the most part rather the productions of individual imaginations, which gained popularity in proportion as they found sympathy, much in the way in which modern poetry makes its way into notice.

Ulrici, in his very elaborate work on the history of Greek poetry, gives two as the principal sources from which lyric poetry was derived—religious worship, and the individual feelings of the people; the first of which elements is traceable in one of the two kinds of epic poetry, which we named *hieratic*, while the second is that in which consists the difference between epic and lyric poetry. He proceeds to divide Greek lyric into the Doric, Æolic, and Ionic kinds: which correspond nearly, the first to what is to be found in choruses; the second to love-songs, such as Sappho's, and drinking-songs, or *scolia*; and the third to the elegy, epigram, and satire.

It has been remarked that both in epic and in lyric poetry the Romans possessed nothing like a school of poets, while in Greece there was a regular progression from epic to lyric schools, each of which supplied many individuals grouped round a principal figure in each class. Virgil and Lucan are the types of Roman epic poetry, and Horace stands almost alone as a lyric poet. But to attempt to give a history of Roman lyric would be little else than to enumerate every man who wrote verses from Ennius downwards, for almost every one of them attempted that as well as all other kinds of poetry. The whole of Latin poetry was in fact on a Greek model, even the most original of the Latin poets having borrowed his metres, though he might make everything else his own.

It might perhaps startle any one to be told that satire is a branch of lyric poetry, and that the most important branch of Roman lyric is satire. But a careful review of the definition with which we started cannot fail to explain this. Satire is essentially lyrical or subjective

in its nature, and the Roman satire more so than the Greek, inasmuch as it partakes far less of the nature of lampoon or ludicrous description, and deals more with general than with individual traits of character. In their satire it is that we must look for information on Roman modes of thought and feeling. It was, or at least appears to us to have been, the only outlet which the Imperial tyranny gave to the free and noble spirit of Rome in her best days, and it is quite astonishing how far this liberty was employed. What it was in earlier days we cannot tell, except as far as Horace's description of Lucilius avails. The words may mean almost anything, but we should be inclined to suppose that it partook much more of the nature of lampoon than in later times. To the satire we may add its powerful auxiliary the epigram, the same in name but very different in nature from its Greek fellow, which ought rather to be called epigraph, or even epitaph.

The Horatian lyrics merged in the later ages of the empire into a species of poetry much neglected, we mean the rhyming verses of the monks, which often contain Hebrew sublimity expressed in most sonorous verses. They are curious as affording the best specimen of the transition from scansion to accent, that is, from the antique to the modern rule of versification.

English lyrical poetry is late in its full development, for to call our ballads lyrical is a misnomer, seeing that the prose and poetical romances often give exactly the same story in another shape. We need go no further than the ballad 'Mort d'Arthur,' so well known to readers of Percy's 'Reliques.' At the same time, though the form of these ballads is mostly narrative or epical, there is often a strong admixture of lyrical feeling, as in 'The Jew's Daughter,' 'Sir Cauline,' and others. Scarcely any poems occur before the time of Milton deserving the title of lyrical, except perhaps some of Giles and Phineas Fletcher's works and Shakspeare's sonnets. In 'Lycidas,' 'Il Penseroso,' and 'L'Allegro,' we see almost the first, and perhaps the most beautiful examples our language can boast. The prevalence of French taste until the revival of poetry at the close of the last century gave so artificial a character to the works of Dryden, Pope, and their successors, that we can hardly give the title of lyrical to any of them except the satires and a few fine odes. In our own day Wordsworth and Coleridge are too well known to require that we should point out how exclusively lyrical is the tendency of their works. Shelley has combined more of what is called sensuous beauty with the rest of the qualities requisite to make up a lyrical poet; and, among living poets, Tennyson may perhaps be mentioned as the greatest of lyrical poets.

(Ulrici's *Geschichte der Hellenischen Dichtkunst*; Dunlop's *Hist. of Roman Literature*.)

LYRICS are those verses which are commonly used in lyrical poetry. Such are those of Pindar, of Horace's odes, and of the tragic and comic choruses. They are generally short, in order, as is said, to agree better with the time of any music which might have been intended to accompany them. The old grammarians divided all verses into those in which the metre was repeated in each line (*κατὰ στίχον*), such as hexameters, iambs, and trochaics; and those which require more lines than one to make up a system (*κατὰ σύστημα*), as in the case of Sapphic or Alcaic verses, or a choric strophe. The latter division contains almost all the lyric metres known, including nearly all Horace's odes, all Pindar's, and all the choruses and even anapestic systems. Of these strophes a further division has been made, into *longer*, such as Pindar, Stesichorus, Simonides, and the Greek dramatists employed; and *shorter*, such as those of the earlier Ionian and Æolian poets, of their imitators, and of Seneca, besides rare examples in the Greek dramatists.

Hermann further distinguishes the longer strophes into Dorian, Æolian, and Lydian, of which he gives examples from Pindar to prove that the first was used where impressive majesty was requisite, the second to give a notion of rapidity and vehemence, and the third as possessing part of the qualities of each.

A question has arisen, and it is at all events a curious point, why lyrical poems are generally divided into lines so much shorter than heroic. That such was the case in Greek and Roman poetry is certain, and it is not explained by saying that they were sung to an accompaniment, for surely there is just as much reason to suppose that Homer's long hexameters were chanted as Anacreon's short iambs, and music might be as well adapted to one as to the other.

LYTTA. [CANTHARIDES.]

M

M is the labial letter of the liquid series. For the various forms of the characters by which it has been denoted in the chief European languages, see ALPHABET.

The changes to which it is liable are chiefly as follows:—

1. *M* is interchanged with *n*. Thus *m*, at the end of Latin cases and tenses, is generally represented by an *n* in Greek. Similarly the German dative *ihm* and accusative *ihn* have been confounded in the English *him*, which is at once dative and accusative. So again the German *boden*, *busen*, *besen*, *faden*, are in English, *bottom*, *bosom*, *besom* or *broom*, *fathom*. And even in the Greek language, notwithstanding its aversion to a final *m*, inscriptions exhibit such forms as *τομ βασιλεα*, *αιθηρ μεμ φουχας*, &c., where the nasal is modified so as to accord with the initial letter of the following word.

2. *M* with *b*. Thus in Latin, *hiems* co-exists with *hibernus*, *tumeo* with *tuber*, *glomus* with *globus*, *fama* with *fabula*. This interchange explains the form of *summus*, the superlative of *sub*, of *sumo* for *subimo*, and perhaps that of *melior*, as the comparative of *benus* or *belus*, the old form of *bonus*; whence *bene*, *bellus*, *βελτερος*, *βελτιστος*, *βεντιστος*, &c. Again *Spotos* is equivalent to *μπος*, and so related to the Latin *mor-i* and the Sanskrit *mri*. In our own language *husband* is a corruption of *houseman*, *dominus*, the correlative of *housewife*.

3. *M* with *p*. Hence the Greek forms *ομα*, *τετυμμαι*, &c., for *οπμα*, *τετυπμαι*, &c. So the Greek preposition *μετα* has a form *πεδα*, and the Greek *μολυβδος* is in Latin *plumbum*.

4. *M* with *v*. This is particularly the case in the Welsh language. Hence the name *Roman* was transferred into that tongue with a *v* (or rather an *f*, which is pronounced as *v*) in place of the *m*; and the Latin *amnis* is believed to be identical with the Welsh *Afon*, pronounced *Avon*. The Latin language too has *promulgare*, apparently for *provulgare*.

5. *M* with *w* probably. This interchange follows easily from the last, and is a natural step towards the next. The German *mit* seems to be identical with our own *with*. In Greek too *μια*, "one," and the particle *μεν* (which also appears to denote "one," and so to correspond to *δε*, "two," probably a corruption of *δυο*), seem to have passed through a form *Fia*, *Fev*, before they became *ia* and *ev*. Compare the old Latin *oeno* and the English *one* as it is pronounced.

6. *M* disappearing. This appears to have been the case even at the beginning of words. See what is said above; and compare the Greek *μεχρις* with *αχρις*, *μοχλιζω* with *οχλιζω*, the Latin *manus* with the Teutonic *hand*, the Latin *mere-re* with the English *earn*. At the end of words at least, the loss of an *m* is very common, particularly after *o*. Thus the Greek and Latin verb often has the first person ending in *o*, where analogy would lead to *om*; *scribo*, *τυπω*. Compare in Latin the words *sum*, *inquam*, besides the other tenses *scribebam*, *scribam*, &c.; and in Greek the middle form *τυπτομ-αι*, *τυπτεσ-αι*, *τυπτετ-αι*, which would seem to have been formed from an old active, *τυπτομ*, *τυπτες*, *τυπτετ*, with the addition of a fixed suffix denoting *self*. In Latin all the adverbs ending in *o*, signifying *motion to*, appear to have lost an *m*, namely, *quo*, *eo*, &c. Hence *adeo*, *quoad*, occur in conjunction with a preposition which elsewhere requires an accusative. Again, an *m* has been lost in *postea*, *antea*, *postilla*, &c.; compare *postquam*, *antequam*, &c. Lastly, the use of *refert mea*, *refert Ciceronis*, *interest mea*, &c., are probably to be explained by the full forms, *rem fert meam*, *rem fert Ciceronis*, *inter rem est meam*. Such a use of *res* accords well with the phrases, *in rem meam est*, *e re tua est*.

7. *M*, like the other liquids, but not so frequently, is liable to change its position with regard to the vowel of a root. Thus in Greek the root *τεμ*, *cut*, may take the form *τμη*; and *δαμα-ω* has derivatives where the *μ* is next to the *δ*.

The letter *M*, or rather a symbol somewhat like it, for which modern printers have found it convenient to substitute that letter, was used by the Romans to denote a thousand. It is commonly said that this character was thus used because it is the initial of *mille*; but see NUMERALS.

MACE, originally a club of metal, whence it derived its name of *Maçe* or *Maçue*, and whence its diminutive *Mazuelle* is also derived. In a more ornamental form it is used as an ensign of authority borne before magistrates. Of this last kind is the mace placed before the Speaker of the House of Commons whilst that officer presides at the sittings of the House. When any other member presides, as in a "Committee of the whole House," the mace is laid under the table. Cromwell's direction to "remove that bauble," when he dissolved the Long Parliament, is familiar to every one. It was until lately commonly supposed, that the actual mace to which he referred, was that presented by Charles II. to the Royal Society, to be placed before the President at the meetings of the society, and without which no meeting is legal. But this has been shown to be an error by Mr. Weld, the secretary, in his 'History of the Royal Society' (vol. i. p. 150, &c.). The mace presented to the Royal Society was a new one, made for the purpose. The

old mace of the House of Commons appears to have been broken, melted, and sold by order of the House, August 9, 1649.

The mace as a military weapon was peculiarly appropriated to the cavalry, and in the Bayeux tapestry several are represented in the hands of the combatants. It is not clear when the fashion of suspending them from the saddle-bow for occasional use was first introduced into Europe, but as it seems to have been borrowed from the Asiatics, we may perhaps assign it to the middle of the 13th century. Muratori observes that in a close conflict of cavalry it was exceedingly difficult to overthrow or wound powerful men in armour sitting on horseback, for their persons, being enveloped in hauberks, helmets, and other iron coverings, eluded the power of swords, darts, arrows, and such like weapons. For this reason it was usual to strike men so defended with iron maces, or to turn the attack on the horses, that by making them fall they might seize the rider; or if he tumbled on the ground, the weight of his armour might render him unable to contend with any effect.

Maces seem to have been much used from the time of Edward II., both in battles and tournaments. Meyrick says all the heavy cavalry were supplied with them in the 15th and 16th centuries, though they sometimes gave way to the short battle-axe and horseman's hammer. The invention of pistols in the reign of Henry VIII. occasioned their disuse in the time of Elizabeth.

Ellis, in his notes to the 'Fabliaux,' says the mace was a common weapon with ecclesiastics, who, in consequence of their tenures, frequently took the field, but were by a canon of the church forbidden to wield the sword.

The word *Mace* is sometimes used by our old writers in the sense of a *sceptre*.

MACERATION is the exposing of any substances, and generally those of vegetable origin, when reduced to coarse powder, to the action of water or any other liquid, without the assistance of heat, in which last circumstance it differs from digestion. The object of maceration is twofold; either merely to soften the parts of the substance operated on, so as to allow of the more ready subsequent action of heat, as when cinnamon or cloves are macerated in water, previously to distillation; or it is employed to dissolve the aromatic parts of a substance, when digestion would not merely dissolve but dissipate them.

MACHICOLATION (in French *Machécoulis*, or *Machicoulis*). This term, which is obviously derived from the two French words *mèches* and *coulér*—to pour down ignited materials—afterwards compounded into the barbarously Latinized one *machicolum*, or *machicolum*, was significantly bestowed on those openings in the parapet of a fortified building through which ignited combustibles (*mèches*), or melted lead, stones, &c., were poured and hurled down upon the besiegers. The apertures were formed in the soffit or under surface of the projecting parapet, which was supported upon corbel stones, the perforations themselves being in the soffit, between those stones. By this ingenious contrivance the besieged were enabled to harass their assailants in a most formidable manner, while they themselves were protected by the parapet and its battlements. Machicolations were frequently confined to particular situations, such as over an entrance gateway and the towers flanking it, or other parts most likely to be assaulted.

MACHINE, an object by the intervention of which a motive power is made to act upon any body and overcome the force by which the latter resists the effort to change its state of rest or motion. A machine differs in no respect from a *tool*, an *instrument*, or an *engine*, and any one of these terms might be used indifferently for the same thing: the word *tool* is, however, generally applied to an object containing in its construction some mechanical power, and which, when in use, is held in the hand of the operator.

The advantage which any machine affords for overcoming resistance, consists in the reaction by which it supports a certain portion of the weight producing that resistance, so that the motive power has only to counteract the remainder. This may be immediately observed in those simple machines called the *mechanical powers*. For example: in the lever, the wheel and axle, and the pulley, the properties of which depend on the theory of parallel forces (when, consequently, of the resistance, the moving power, and the reaction of the machine, some one is equal to the sum of the two others), any convenient portion of the resistance may be made to rest on the point of support, or the point of suspension. Again; in the inclined plane, the wedge, and the screw, the properties of which depend on the theory of forces concurring in a point, the motive power, the resistance, and the reaction of the support, are represented by the three sides of a triangle; and the ratio of the first to either of the others may be varied at pleasure by the construction of the machine.

The powers employed to give motion, through machinery, to any object, are produced by the *muscular strength* of men or animals; th

actions of *weights, springs, wind, water, steam*, or fired *gunpowder*; and these powers may generally be considered as pressures exerted during certain portions of time. Even that power which is produced by a sudden impulse, as when a rammer descending by its weight falls on the head of a pile, is only a pressure existing during an indefinitely short interval of time. The point in any machine to which the moving power is applied is called the *impelled*, and that against which the resistance acts is called the *working point*.

In the employment of any machine a certain portion of the power is expended in overcoming the inertia and friction of the materials, and that which remains is the only efficient force by which the useful effect is to be obtained. Thus, in pushing or drawing a body up an inclined plane, the effective motive power is less than that which is actually expended by as much as is necessary to overcome the inertia of the body and its friction on the plane; and these might be avoided if it were possible or convenient to raise the body vertically to an equal height by the descent of a body of greater weight, when both are connected together by a string passing over a pulley. The loss of power from inertia is doubled when a reciprocating motion exists in the same machine; for a momentary state of rest takes place between every two contrary directions of the movement, and immediately afterwards a new inertia is to be overcome. The retarding forces above mentioned are evidently greater as the quantity of machinery in an engine is augmented; and hence every machine should be as simple as possible consistently with the requisite relation between the moving power and the opposing resistance.

In the construction of machinery it is evident that all abrupt variations of velocity should be prevented, on account of the irregularity which they induce in the action. When, for example, one wheel drives another by means of the teeth on their circumference, the pressure of the teeth takes place wholly on one side of the latter, and the movement may be steady if the teeth are well formed; but on a sudden diminution of the velocity of the driving-wheel, that which is driven, continuing for a time to move with its actual velocity, tends further to retard the movement of the other, and the pressure of the teeth against each other takes place on the opposite side. Thus a shaking motion is produced which diminishes the efficacy of the machine. The disadvantage attending such variations in the movement of the machinery renders it advisable to gain the required effect by continued pressure, if possible, rather than by the employment of percussive forces.

It is also a maxim assented to by engineers that the impelled point of a machine should not be allowed to move with a greater velocity than that with which the motive power can act upon it; since in this case the excess of velocity in the machine will be employed in accelerating the motion of the power, and thus the general acceleration of the machine will suffer a corresponding diminution. The velocities of the impelled and working points should therefore be properly adjusted to the pressures, the inertia, and the friction, in order that all possible advantage may be derived from the machine.

A just estimate of the power of a machine ought to include the effects of all the momentary accelerations and retardations of motion to which it is subject, and all the losses arising from inertia and friction; but as the introduction of these circumstances would excessively complicate the investigation, it is usual to make the measure of the power depend on the condition that the impelled and working points shall be in a state of uniform motion. For then, agreeably to the property of the simple lever, the velocities of those extreme points will be inversely proportional to the forces which would be in equilibrio at the same points; and the rule propounded by Euler is, that in every machine, simple or complex, the pressure at the impelled point, multiplied by the velocity of that point, is equal to the product of the resistance at the working point by the velocity of the same point; or the momentum of resistance (commonly called the *performance* of the machine) is equal to the momentum of impulse. Whatever objection may be made to this rule with respect to the measure of the power in action, no doubt can exist that it affords a correct value of the useful effect; and the latter may therefore be measured by the weight which might be raised by the machine to a given height vertically in a given time. The fact is sufficiently evident when a mass of any material is to be conveyed from one place to another, or when a body is let fall on any object from a given height. It follows that, if an algebraical expression be obtained for the momentum of the resistance in terms involving that resistance, the motive power and the distances of their points of application from the axis of motion, on making the differential of that expression equal to zero, the ratio of the resistance to the moving power, when the useful effect of the machine is a maximum, may be found from the resulting equation.

If M represent the mass of any body moved, w its weight, which is equal to Mg , g ($=32\frac{1}{2}$ feet) expressing the force of gravity; also, if H be the height to which the body may be raised in one second of time, and v the velocity which a body would acquire by falling vertically through a height equal to H , we shall have, by the theory of motions, $v^2 = 2gH$; whence wH (the momentum of resistance, or the useful effect of a machine) $= \frac{1}{2} M v^2$. This last expression is designated the *living*, or *active*, *force* of the body moved; and it expresses the force of a body in motion, in contradistinction to the simple pressure exercised by a body at rest.

It is commonly asserted that, in the employment of machinery, as much is lost in time as is gained in power, or that the momentum of resistance is proportional to the power employed; but this rule requires some modification. It can be shown to hold good in a well-constructed machine when the object moved resists by its inertia only; but if the inertia is but a small part of the resistance, the momentum of the latter, or the work done, is found to increase nearly as the square of the power employed.

The various ingenious contrivances which have been adopted in machines for regulating the velocities, and for converting one species of motion into another, are noticed in the article *WHEELS*.

In investigating the relations between the motive powers and resistances to be overcome, which render the effect produced a maximum with respect to quantity of motion or velocity, or which render the time of the performance a minimum, it is usual to consider that in every machine there is a certain point at which, if the moving power were immediately applied, and a certain point at which, if the resistance to be overcome were immediately applied, the effect produced would be the same as that which is produced by the machine in its actual state. Thus, in a machine consisting of several wheels and axles with which weights are raised by means of ropes passing over their circumferences, the points at which the ropes immediately connected with the moving power and resistance are tangents to the circumferences are those at which the forces are conceived to be applied. Also, if several forces act at once as moving powers, and resistances are to be overcome at once at various points, the resultant of all the forces and that of all the resistances must be taken for the effective moving power and the effective resistance. The points of application of these resultant forces are to be found, and at these points such resultant forces are conceived to be applied: the effects of friction, the rigidity of ropes, and every other impediment to the action of the machine, are also to be estimated and applied as additions to the resistance which is to be overcome; and thus a complex machine is reduced to an equivalent mechanical power of a simple form. The velocities of the points at which these resultant forces are conceived to be applied are equal to the velocities of the power and resistance.

The motion in machines may be of two kinds. On the application of force to a machine previously at rest a certain movement is induced, and this movement for a time is accelerative; but in some machines, after a while, the resisting power and the friction of the materials destroy the acceleration, when, unless the machine is subject to variations of force, as is the case with those which are impelled by the wind or by the force of men or animals, the movement will become uniform. On the other hand, there are machines which are acted on by a constantly accelerative power, as when a weight at one end of a rope passing over a wheel descends from an elevated place and raises a weight attached to the other extremity.

If the velocities of the points of application of the equivalent forces are uniform, a simple equation will express the dynamical equilibrium of the machine; for, F representing the moving power, and v the velocity with which it moves, f the force of resistance and v its velocity, we have in the case of equilibrium

$$Fv = fv;$$

the first member of the equation is frequently designated the *momentum of impulse*, and the second the *effect* produced by the machine.

But the effect of a moving power on a machine in motion is different from that of an equal power on a machine at rest; for the effect produced by any constant power in the former case depends upon its relative velocity, or the difference between its own velocity and that of the machine, and, by dynamics, it varies with the square of the relative velocity. Therefore, in order to introduce the absolute effect of a force into the equation of equilibrium in place of the efficient force, there must be given the velocity which would render the force quite ineffectual, as well as the actual velocity of the point of application: let the former be represented by v' , and the latter by v ; then F' representing the absolute force when the velocity is zero, and F the actual force when the velocity is v (F' being determined by the weight or resistance which is just sufficient to prevent the power from communicating motion to the machine, and v' by the velocity with which the machine can move when the resistance is zero),

$$F' : F :: v'^2 : (v' - v)^2;$$

$$\text{whence } F = F' \frac{(v' - v)^2}{v'^2}.$$

Then the first member of the equation $Fv = fv$ becomes

$$F' \frac{(v' - v)^2}{v'^2} \cdot v :$$

or, putting v' for $v' - v$, which gives $v = v' - v'$, it becomes

$$F' \left(\frac{v'}{v'} \right)^2 (v' - v')$$

Now, in order to find the velocity which is consistent with the production of the greatest effect by the machine, this expression, which represents the equivalent of fv , the efficient action of the machine, is

to be a maximum; therefore, differentiating that expression, v' being the variable, and making the result zero, we have

$$2v' - 3v' = 0; \text{ whence } v' = \frac{2}{3}v'$$

and, by substitution, $v = \frac{1}{3}v'$.

Hence, if the resistance opposed to the machine is susceptible of being varied, it should be rendered such that the velocity v of the point of application of the equivalent force is one-third of the greatest velocity v' which the power can produce if unresisted. Substituting this value of v in the above equation for F we get $F = \frac{4}{9}F'$; therefore Fv , the momentum of impulse, or the effect of the machine, becomes $\frac{4}{27}F'v'$ when that effect is a maximum, the resistance remaining unaltered.

If two bodies are connected together by a flexible line (supposed to be without weight) passing over a pulley at the common summit of a doubly inclined plane, the parts of the line being parallel to the surfaces of the two planes; the relation between the weights may be determined so that the momentum of that which is to be raised by the descent of the other may be a maximum. Let p and w be the weights of the bodies, or the forces of gravity acting on them vertically, and let θ and θ' be the respective inclinations of the planes on which they are placed, to the horizon; then $p \sin. \theta$ and $w \sin. \theta'$ are the forces of gravity on the planes, and consequently $\frac{p \sin. \theta - w \sin. \theta'}{p + w}$ is the accelerative force by which p descends.

Now, by dynamics, the velocity of a body varies with the force and time; therefore, v representing the velocity of p or w , and t the time of motion,

$$v \propto \frac{p \sin. \theta - w \sin. \theta'}{p + w} t,$$

and consequently the momentum wv varies with

$$\frac{pw \sin. \theta - w^2 \sin. \theta'}{p + w} t;$$

this expression is to be a maximum; therefore, differentiating it, w being the variable, and making the result equal to zero, the value of w may be found in terms of p by a quadratic equation: thus, the required relation may be obtained.

If it were required to find, in any machine which when reduced to its most simple state may be considered as a lever or a wheel and axle, the ratio of the velocity of the moving power to that of the resistance to be overcome when the latter is a maximum, the following process may be used.

Let the arms of the supposed lever, or the semi-diameters of the supposed wheel and axle, be represented by r and r' , the power p being applied at the extremity of r , and the resistance w at that of r' . By the nature of the lever, $p = \frac{wr'}{r}$ in the case of equilibrium; therefore,

when the power is such as to produce motion, the motive force may be expressed by $p' = \frac{wr'}{r}$ if applied at the extremity of r . Now, in order

that the momentum of the inertia of w at a distance r' from the fulcrum may be made equivalent to the momentum of inertia of a body at a distance r , on representing such body by p'' , we have $p''r^2 = wr'^2$; whence $p'' = \frac{wr'^2}{r^2}$: the whole inertia to be overcome, if

applied at a distance r from the fulcrum, will therefore be $p + \frac{wr'^2}{r^2}$, and the accelerative force at the extremity of r will be

$$\frac{p + \frac{wr'}{r}}{p + \frac{wr'^2}{r^2}} \quad \text{or} \quad \frac{r^2p - wr'r}{r^2p + wr'^2}.$$

But, by dynamics, the velocity of a body varies with the force and time; therefore, representing the velocity at the end of the arm r by v ,

$$v \propto \frac{r^2p - wr'r}{r^2p + wr'^2} t;$$

in order to obtain the velocity at the end of the arm r , the expression for v must be reduced in the ratio of r to r' ; therefore the velocity at the latter extremity varies with

$$\frac{r'r'p - r'^2w}{r^2p + wr'^2} t.$$

This expression is to be a maximum; therefore, on differentiating it, r' being the variable, and making the result equal to zero, there will be obtained the ratio of r to r' (which is the same as that of the velocities of p and w) consistently with the condition that the velocity of w is a maximum.

In the theory of machines, the modification of motion and the

modification of force take place together, and are connected by certain laws; but in the study of the subject there is an advantage in first considering the principles of the modification of motion, which are based upon a branch of geometry called *cinematics*, and afterwards considering the principles of the combined modification of motion and force, which are founded both on geometry and on the laws of dynamics. The separation of cinematics from dynamics is due mainly to Monge, Ampère, and Willis. The modern view of the subject of applied mechanics may be best studied in the following works: Poncelet, 'Mécanique Industrielle'; Morin, 'Notions Fondamentales de Mécanique'; Willis, 'On the Principles of Mechanism'; Moseley, 'Mechanics of Engineering and Architecture'; Whewell, 'Mechanics of Engineering'; Rankine, 'On Applied Mechanics,' and on 'Prime Movers.'

MACHINERY. It is proposed to consider in this article the influence which is exercised by machinery upon the general interests of mankind, and especially upon the well-being of different classes of society. There is no subject in the present age which is more deserving of attention; and none perhaps in which all classes are so much concerned. Whatever theoretical opinions may be entertained by speculative men, the use of machinery in aid of human labour, or, as some contend, instead of it, is rapidly increasing and cannot be restrained; it is right therefore for all men to endeavour to judge for themselves in what manner it is valuable to society, and whether the injuries attributed to it be real or imaginary. By some, every new machine is viewed as an addition to the wealth and resources of a country; by others it is regarded as a hateful rival of human industry—as iron contending with straining sinews—as steam struggling against the life and blood of man. The one view is full of hope and promise; the other is fraught with gloom and sadness. One would present society advancing in wealth and comfort; the other would show it descending faster and faster into wretchedness. But even those who believe that the inventive faculties of men have been engaged in devising for themselves a curse, would gladly be convinced that cheerful anticipations of good are consistent with sound philosophy.

The influence of machinery is of two kinds; 1st, as it affects the production and consumption of commodities; and 2ndly, as it affects the employment of labour.

As regards production, the effects of machinery have been well described to be the same "as if every man among us had become suddenly much stronger and more industrious." ('Results of Machinery,' 7th edit. p. 35.) If, by the aid of machinery, ten men can perform the work of twenty, and perform it better and more quickly, the products of their labour are as much increased as if they had really "become suddenly much stronger and more industrious," and, it may be added, more skilful. Thus production, which is the object of all labour, is more abundant, and society enjoys the results of industry at a less cost. Who can doubt that this is a great benefit, unless it be attended with evils which are not at first perceptible? No man labours more than is necessary to effect his object, and his constant desire is to contrive modes of saving his own physical exertions. A rich soil and a fine climate are universally esteemed as blessings because the people enjoy abundance with comparatively little labour. A poor soil and bad climate are evils, because the husbandman must labour much, though the produce of his industry be small.

Labour without adequate results is always regarded as a curse, and almost every human invention, from the earliest times, has had for its objects the saving of labour and the increase of production. Horses and other beasts of burden were made to work for man; to bear loads which otherwise they must have borne themselves; to draw the plough which otherwise their own strength must have forced through the soil. To the same object all nature has been made subservient. The stream turns the mill, and does the work of man; the wind performs the same office. A boat is built to save men the labour of carrying their goods to a distance, and it is less labour to row the boat than to carry its cargo: but rowing is laborious, and sails were invented that the wind should do the work of man. In all other matters it has been the same. Man is weak in body, and ill endowed by nature with the means of self-preservation and subsistence. Many animals are stronger and most animals are more active than himself: they can pursue their prey with more certainty, they are armed with weapons of offence and defence, and they need no shelter from the weather but that which nature has provided; their own powers and their own instinct suffice for their preservation. But man was created naked and defenceless. To live he must invent, and reason was given to him that he might force all nature into his service. His teeth and nails were powerless against the fangs and claws of the wild beast; but his hands were formed with wondrous aptitude for executing the tasks which reason set them. He invented tools and implements and weapons, and all nature became his slave. He was now able to make his own strength effect as much as if he had become stronger and more industrious. He produced more for his own comfort and subsistence, with little labour, than the greatest exertions could otherwise have obtained for him. Every successive invention has made him more powerful, has increased his strength, and multiplied the productions of his industry; and at length the giant power of steam has peopled the world with inanimate slaves, who do his work faster and better than he did it himself with the greatest labour and the most ingenious tools.

The flint and fish-bone of the savage, the tool of the workman, and the steam-engine of the manufacturer, have but one common object—to save the labour of man and to render it more productive: but that is the most perfect invention which attains this object the most effectually. Can any one doubt the advantage of abundant production? It needs but a few words to point out its benefit. Whether it be for evil or for good, we are not satisfied with the enjoyment of the common necessities of life; we all desire comforts, luxuries, and ornament; and in proportion as we desire them do we become civilised. There are many who sneer at civilisation, and unhappily it has its vices, its follies, and its absurdities; but it seems the law of our nature to advance to that state, and with the increase of artificial wants our intellects become more active and enlightened, refinement of manners succeeds to barbarism, and all those moral qualities for which man is distinguished, become developed. We may conceive some Utopia in which all the noble parts of man's nature are cultivated, while his wants remain simple and easily satisfied, but the world we live in presents another picture. We might wish it were otherwise; but it is in vain to deny that refinement is the accompaniment and, in some degree, the consequence of riches, and brutality the condition of those people who have not been elevated by the increase of wealth. It follows therefore, that to multiply the objects of comfort and enjoyment which human industry can produce, is to improve the condition of mankind, to raise them in the scale of moral and intellectual being, and to minister to their enjoyment of life. It is quite consistent to deprecate the vices and follies which are ever associated with our craving for new possessions, while we observe the benefits resulting from the desire to progress in improvement. Throughout the world good and evil are found side by side; but the good, as we would fain believe, preponderates.

When once it is admitted that men are to be decently housed and clothed, and are to surround themselves with such comforts as they can obtain, it is clear that the more easily they can obtain them, and the more generally such possessions are enjoyed, the more completely are the objects of civilised life secured. If all men could obtain them easily, there would be no poverty, and infinitely less vice. Machinery, by diminishing the amount of labour required for the production of commodities, lowers their price and renders them more universally accessible to all classes of society. Working-men no longer toil for the rich alone, but they participate in the results of their own industry. If they desire such luxuries, "purple and fine linen" are not beyond their reach; and their dwellings are more commodious and often more elegant than were the houses of the rich three centuries ago. If this increased facility of acquiring the comforts of life had been accompanied by greater prudence and frugality, we believe that the beneficial results of machinery would have been conspicuously shown by the improved condition of all the working-classes of this country. Cheap production is more beneficial to the poor than to the rich. The rich man is certain of gratifying most of his wants, but the poor man is constantly obliged to forego one enjoyment in order to obtain another. If his shoes or his coat be worn out, his dinners must be stinted perhaps until he can pay for a fresh supply; and thus, unless his wages be reduced in consequence of the cheapness of such articles, it is beyond all question that cheapness is an extraordinary benefit to him, the money which he saves in the purchase of one cheap article is laid out upon another, and without privation or suffering he satisfies the wants which custom has made imperative. In short he is no longer poor.

These facts are undeniable; but it is alleged that machinery not only makes articles abundant and cheap, but multiplies them beyond the wants of the world, and by causing gluts brings ruin and misery upon the working classes. For reasons explained elsewhere [DEMAND AND SUPPLY] a universal glut of all commodities is impossible: the more men produce, the more they have to offer in exchange, and their wants are only limited by their means of purchasing. But particular commodities are frequently produced in excess, and a glut of the market ensues. In causing such gluts machinery is a powerful agent, but only in the same manner as all labour would be, if applied in excess. The results would be precisely the same if too many men were employed in any department of industry; they would produce more than there was a demand for, and their goods would fall in value or be unsaleable. Commodities produced by machinery are subject to the same laws as govern all other commodities. If the supply of them exceed the demand, they are depreciated in value; but the power of producing with facility does not necessarily occasion an excess of production: it must be applied with caution, and its use be properly learned by experience. Suppose that the soil of any isolated country were extraordinarily fertile and the population very small; but that without considering these circumstances the people were to cultivate the whole of their land and bestow upon it all their skill and labour. An excess of food would be the result—more than could be eaten within the year; much would be wasted or sold without profit, and much laid up in store for another season. The husbandmen would be disappointed at the unfortunate results of their industry, but would they complain of the fertility of the soil? It would not be the soil that had caused the glut, but their own misapplied exertions; and so it is with machinery, which like a fertile soil gives forth abundance: its capabilities are known and its advantages ought to be appreciated; but if its productiveness be brought into excessive activity, it causes the evils of a glut.

The influence of machinery upon the production and consumption of commodities need not be followed any further. It increases the common stock of wealth in the world and is capable of multiplying indefinitely the sources of human enjoyment. But these benefits will be neutralised if, while it cheapens production, it has a tendency to diminish the means of employment for the people, and lower the wages of labour;—and this leads us to the second part of our inquiry.

The invention of a machine which should immediately do the work of many men employed in a particular trade would certainly, in the first instance, diminish employment in that trade. Several men would be turned off to seek employment in other trades, and much individual suffering would be occasioned. There have been frequent instances of such a result, and so far as the immediate interests of the particular sufferers are concerned, it is an evil which cannot be too much lamented. In their case machinery is like a rival bidding against their labour, and is as injurious to them as if a fresh set of workmen had supplanted them in the service of their employer. But great as this evil is (and we would not underrate it) it is of comparatively rare occurrence and of short duration. If the invention of the machine caused no more production than the labour of the workmen had previously accomplished, the labour of a certain number of men would be permanently displaced: but as an equal quantity of goods is produced at a less cost of labour, their price is reduced, and their consumption consequently encouraged. An increased supply is thus called for, and more workmen are again required in the trade. In this manner the demand for increased production corrects the tendency which machinery would otherwise have to displace labour permanently. Even the temporary displacement which frequently occurs is less extensive than might be supposed. Machines are rarely invented which at once dispense with many workmen. They are at first imperfect, and of limited power: they make the labour of the workmen more efficient: but do not become substitutes for labour. Thus, even if the demand for commodities were not increased, the displacement of labour would be very limited and deferred to a distant period: but as an increased demand almost invariably follows every successive improvement in machinery, it will be found, practically, that more operatives are employed in every branch of manufacture, after the introduction of improved machinery than before.

Of this fact we shall offer some examples presently; but here it may be necessary to allude to the case of the hand-loom weavers, which is constantly adduced in proof of the supposed evils of machinery. Their unhappy condition can scarcely be overstated, nor can it be denied that it has been caused by machinery: but it must be recollected that while they have vainly contended against machinery—like pigmies against a giant—hundreds of thousands of other classes, unaccustomed to the labour of operatives, have gained a profitable employment by working with it, in the same trade as themselves. No one can suppose that the labour of the hands could compete with the power of steam, and the real cause of their distress is, that instead of adapting the form of their industry to the altered circumstances of their trade, they have continued to work, like an Indian caste, with the same rude implements which their fathers used before them. Their case is the same as that of a miller who should persist in grinding corn by hand, while his neighbours were building mills upon a rapid stream which ran beside his garden. His own ignorance or obstinacy, and not the water-wheel, would be the cause of the failure of his trade.

If the case of the hand-loom weavers be adduced as an example of the permanent displacement of labour by machinery, and if it be contended that it is the natural result of machinery to diminish employment in other trades in the same manner, we must necessarily infer that wherever machinery has been largely introduced into any trade, the number of persons supported by it must have been diminished. We should infer that the agricultural population of this country must have been rapidly increasing, while the population engaged in those branches of manufacture in which steam-power is used must have been falling off or increasing less rapidly. The correctness of such an inference may be estimated from the following facts:—

In no trades has machinery been so extensively introduced as in the manufacture of cotton, wool, and silk, and nowhere has the population increased so rapidly as in the principal seats of these manufactures. The census returns of 1801, 1841, and 1851, show the following remarkable increase of population in some of the chief manufacturing boroughs, in which the borough boundary is taken:—Manchester, from 90,399 to 240,367, and, with Salford in 1851, to 401,231; Liverpool, (whose prosperity depends mainly on the cotton trade) from 79,722, to 282,656, and 375,955; Stockport, from 19,250 in 1811, to 50,154 and 53,835; Leeds, from 53,162 to 151,063, and 172,270; Bradford (Yorkshire) from 6393 to 66,508 and 103,778; Bolton, from 17,416 to 50,163 and 61,171; Huddersfield, from 7268 to 24,931 and 30,880; and Macclesfield, from 8743 to 32,523 and 39,048. In Scotland the same results have followed from the use of machinery. The population of Glasgow increased from 77,058 to 261,004 and 329,097; Dundee, from 27,396, to 64,629 and 78,931; and Greenock from 17,458 to 36,936 and (the parliamentary borough only) 36,689.

Thus far of the manufactures of cotton, wool, and silk. The seats of the iron and hardware trades exhibit similar results. In the same periods Birmingham increased from 73,670 to 181,116 and 232,841; Sheffield, from 31,314 to 109,597 and 135,310; Wolverhampton, from

12,565 to 92,943 and 119,748; Merthyr Tydvil, from 7705 to 34,977 and 63,080; and West Bromwich from 5687 to 26,121 and 34,591.

A large extension of employment in any one branch, necessarily produces accessions in most others. It may therefore be not uninteresting to state the number of persons directly engaged in the staple employment of the towns named. In Manchester and Salford, 65,000 are engaged in the manufacture of cotton, silk, and wool; at Stockport, 17,000, cotton; at Leeds, wool and flax, 23,714; at Bradford, worsted and stuff, 33,000; at Bolton, cotton, 14,500; at Huddersfield, woollen cloth, 13,935; Macclesfield, silk, 14,500; Glasgow, where the employments are more miscellaneous, cotton and flax give employment to only 14,830 persons; Dundee, in linen and flax, 19,742. The various metal trades employ in Birmingham, 26,900; in Sheffield, 20,000; in Wolverhampton, 10,530; Merthyr Tydvil, 13,412; and West Bromwich, 7032; in the last-named three the coal-miners are included.

In this extraordinary ratio has the population increased in the seats of our staple manufactures, which by the aid of machinery have supplied the whole world with articles wrought by the industry of our people. Let us now compare these places with those agricultural counties in which machinery has exercised the least influence, and let us see if the absence of machinery has been equally favourable to the support of a growing population. In the same period, Devonshire, Somersetshire, Dorsetshire, Norfolk, Suffolk, Essex, and Lincolnshire, have increased on an average little above 50 per cent.; while, setting aside the extraordinary increase exhibited in the particular towns already enumerated, the population of six manufacturing counties, viz. Lancaster, Middlesex, York (W. R.), Stafford, Chester, and Durham, including all the agriculturists, increased nearly 120 per cent.

These facts prove conclusively that machinery, so far from diminishing the aggregate employment of labour in those trades in which it is used, increases it in an extraordinary degree. And not only does it give employment to larger numbers of persons, but their wages are considerably higher. We will not stop to compare the income of an agricultural labourer with that of operatives engaged in the infinite variety of trades carried on in manufacturing towns, in connection with machinery: but it is sufficient to ask, whence has come the manufacturing population? Its natural growth would have been comparatively insignificant if thousands had not been attracted to the towns from other places. And what could have induced them to leave their homes and engage in new trades but the encouragement offered by more certain employment and higher wages?

It has been shown that machinery has had a beneficial influence upon the employment of labour in the particular trades in which it has been used, and it now remains to consider its effects upon the employment of labour in other trades. In the first place, a few of its obvious results may be noticed. For example, the manufacture and repair of machinery alone gives employment, directly and indirectly, to vast numbers of persons who are unconnected with the particular trades in which the machinery itself is used. Again, the production of all commodities is increased by machinery; and thus the producers of the raw materials of manufactures, the carriers of goods by land and sea, the merchants, the retail-dealers, their clerks, porters, and others, must find more employment. It is clear also, that while the manufacturing and commercial population are thus increased by the use of machinery, the cultivators of the soil must receive more employment in supplying them with food.

In this and other ways the general employment of labour is directly extended by machinery. At the same time the application of machinery to existing branches of industry creates new trades and distributes capital into other enterprises which afford employment for new descriptions of labour. A hundred examples of this fact might be cited; of which railways and steam navigation are amongst the most remarkable; but such examples will be superfluous if it can be shown that it is the necessary result of the use of machinery to apply capital to new enterprises. It has been said that machinery cheapens production by reducing the amount of labour expended upon it: it follows that a less amount of capital with the aid of machinery will produce as much as a larger capital without such aid. A portion of capital is thus disengaged, either for increased production in the same trade, or for application to new speculations. In some way it must be employed, or it will yield no profit, and in some form or other it must be ultimately expended in labour. As long as a person can extend the accustomed operations of his own trade with a profit, he is disposed to do so; but as soon as he finds them less profitable than other investments, he changes the direction of his capital, and seeks new modes of increasing his profits.

There is no truth more certain than that the employment of labour is small or great according to the proportion which capital bears to the number of labourers. Capital is the fund which supports labour, and which must employ it or be unproductive; and thus, if in any country capital be increasing more rapidly than the population, employment will be abundant and wages high; if less rapidly, employment will be scarce and wages low. In the one case, capitalists will be bidding high for labour; in the other, labourers will be bidding against each other for employment. Accumulation of capital is therefore highly conducive to the interests of the labouring population generally, and the use of machinery is especially favourable to accumulation, as may be shown by a simple example. Suppose a man to have a capital of

10,000*l.*, which he is expending annually upon labour in a particular trade, and that his profits are 10 per cent., or 1000*l.* a-year. Each year his whole capital is expended, and his means of accumulation are thus restricted to a portion of his annual profits only. But let him invent a machine to facilitate his business, and his position is immediately changed. If this machine should cost 5000*l.*, and the other 5000*l.* be still expended in labour, he may be said to have saved one half of his entire capital in a single year; for instead of spending the whole of it as before, in labour, he is possessed of a durable property which, at a small annual cost, will last for ten or probably twenty years. Nor can it be said that this saving is effected at the expense of labour; for the owner of the machine is placed in a new position in respect to his profits, which prevents him from securing to himself the difference between the amount paid now and that previously paid for labour. To gain a profit of 10 per cent. it had been necessary for him, before the invention of the machine, to realise 11,000*l.* annually, being his whole capital and the profits upon it: but now, in order to obtain the same profit, it is sufficient if he realise 6500*l.* only: namely, 500*l.* profit upon his fixed capital of 5000*l.*; 500*l.* for repairs, and wear and tear, calculated at 10 per cent.; and 5500*l.* to replace the sum spent upon labour, with a profit of 10 per cent. He would realise the whole 11,000*l.* as before, if he were able; but he is restrained by competition, which levels the profits of trade. For some time he will most probably obtain more than 10 per cent. profit, and so long as he is able to do this, his means of accumulating fresh capital in addition to his machine will be increased, which capital will be expended upon additional labour. But when his profits had been reduced to their former level by competition, society has gained in the price of his goods 4500*l.* a-year, being the difference between 11,000*l.* formerly realised by him, and 6500*l.* his present return. But is this amount thus gained by society lost to the labourer? Unquestionably not. As a consumer, he participates in the advantage of low prices, while the amount saved by the community in the purchase of one commodity must be expended upon others which can only be produced by labour. It cannot be too often repeated, that all capital is ultimately expended upon labour; and whether it be accumulated by individuals in large sums, or distributed in small portions throughout the community, directly or indirectly it passes through the hands of those who labour. If a manufacturer accumulates by means of higher profits, he employs more labour; if the community save by low prices, they employ more labour in other forms. So long as the capital is in existence, it is certain to have an influence upon the general market for labour.

We are now speaking not of the interests of particular workmen to whose temporary sufferings caused by the use of machinery we have already adverted, but of the general and permanent interests of the working population of a country. As regards these, the statistics of British industry amply confirm all reasoning from principles, and prove beyond a doubt that machinery has had a beneficial influence upon the employment and wages of labour. Any one who will reflect upon the facts which have been noticed above, as disclosed by the Census [CENSUS], can scarcely fail to arrive at the conclusion that without machinery England could not have supported her present population, or could only have supported them in poverty and wretchedness. Nor must the degradation of a part of the manufacturing population be thoughtlessly attributed to machinery, instead of to moral and social causes, which are independent of it. Into these causes it would be out of place, at present, to inquire; but enough has been said to show, 1st, that machinery by increasing production multiplies the sources of enjoyment, and places them within the reach of a greater number of persons; and 2ndly, that by giving increased employment to labour it enables more persons to enjoy those comforts which it has itself created. These are the elements of social prosperity, and if evils have sprung up with it, like tares with wheat, it is not machinery which has caused them. Wherever the influence of machinery has been felt, wealth has advanced with rapid strides; and though in too many cases religion, virtue, and enlightenment may have lagged behind, the tardiness of their progress is to be ascribed, not to machinery, but to the faulty institutions of men.

MACHINERY, COMPOSITION OF. The composition of a machine is usually understood, by writers on this branch of the arts, to involve all the detailed arrangements by which the power exerted, however that power be obtained, is made to produce the required effects; or in other words, those contrivances by which the initial force is transmitted with the smallest loss, or with the least waste of material. From the endless modifications of machinery it must evidently be impossible here to notice all their component parts; but a few general observations upon wheels, shafts and spindles, cranks and eccentrics, drums and band wheels, clutches and coupling-gearing, may suffice to call attention to some of the leading principles connected with the composition of machinery.

Wheelwork, whereby the power is transmitted by means of teeth working into one another, is usually known under the name of gearing, and this part of the subject has already been noticed [GEARING]; but it may perhaps be worth while to add that wheels are technically subdivided into toothed, trundle, pin, crown, annular, and bevelled wheels, according to the shape, or the position, of the parts gearing, or working, into one another. Sometimes also a pinion may be made to

revolve in, or upon, a straight piece of gearing, for the purpose of changing a continuous rotary to a horizontal motion, or *vice versa*; or, again, the wheels may be susceptible of motion in alternate directions, or they may be intended only to revolve in one, in which case they either are made of such a form as themselves to act as ratchet wheels, or they are prevented from turning in the wrong direction by such a contrivance. In some cases also motion is given by the mere friction of the peripheries of the wheels upon one another, but evidently this can only be accomplished in very small machinery, or where the force to be transmitted is small. The principles upon which wheels of the various descriptions above-mentioned must be formed have been elaborately discussed in Camus, 'On the Teeth of Wheels,' by J. T. Hawkins, 1842; Moseley's 'Mechanical Principles of Engineering,' 1843; Warr's 'Dynamics,' &c., 1851; they will also be found in a condensed form under GEARING; MACHINE; WHEELS, TEETH OF.

Spindles, or shafts, are the axes upon which the various wheels are fixed, and by which the initial motion is distributed as may be desired. They may be of wood, or of metal; and if of the latter class of materials, either solid or hollow, square, hexagonal, or circular, as may be desired; the object to be aimed at being, in all cases, to make the shaft as light as possible consistently with the requisite degree of strength, and to reduce the dimension of the bearings to the minimum in order to diminish the friction. When shafts are made to revolve on a vertical axis, they turn on a pivot, or gudgeon; when horizontal shafts of great length are used, they turn in plummer blocks, or carriages. As it has been found practically that two loaded surfaces work upon one another with the greatest amount of friction when they are of the same material, it is usual to make the bushes or steps, in which the shafts or gudgeons work, of a different material to those parts of the machinery themselves; or in fact to make iron work on brass or gun metal, wood upon iron, &c.

Cranks and eccentrics are the contrivances by means of which, in addition to wheels, the direction, or the nature, of the initial motion of a machine is transmitted to the work; or in other words, by means of which circular, and rectilinear, motion are reciprocally converted, or uniform velocity is changed into a variable one. The bell crank lever is the best illustration of the parts of machinery for transmitting a rectilinear motion in one direction to a shaft working in another direction; and according as the other end of that shaft may be attached to a crank working on a fixed axle around which it may revolve freely, or be attached to a part of the machine susceptible only of rectilinear motion, it will be able to convert the original rectilinear motion into another one of the same description, or into a curvilinear motion. The rack and pinion have been already cited as an illustration of the means of converting circular into rectilinear motion; and the common bow drill may be cited as an ordinarily adopted method of converting alternate rectilinear motion into alternate circular motion. Eccentric wheels are, however, the most generally adopted means of converting curvilinear into rectilinear motion, and they may be either formed of circular wheels keyed upon shafts, whose axes do not pass through the centre of the former; or they may be what are called heart-shaped eccentrics; or they may communicate movement by pins working in slots. The cam is a contrivance frequently used for the purpose of converting continuous circular motion into an alternate vertical one, and this is effected in the case of tilt hammers by means of a series of eccentrics able to lift a lever, fixed at one end, in a gradual manner through a path corresponding to the highest point of the cam itself, after attaining which the lever is suddenly released, and of course falls. Varying rectilinear motion may be produced by modification in the shape of the cam in any way which may be required; and there are countless modifications of the traverses of machinery, whereby continued alternate motion is obtained from wheels or axles revolving in a circle. A reversing motion may be obtained by the use of a sliding bush working in a groove; and in the numerous tool-making machines of Mr. Whitworth, every description of change of motion from circular to horizontal may be observed. The crank is, it may be added, the most important element of machinery for the purpose of converting an alternate vertical, or horizontal, motion round a fixed centre, into a circular motion; and the parallel rods, so universally applied to connect the piston heads to the balance beams of steam engines, may be cited as amongst the most important combinations for the conversion of alternate vertical motion into a partial alternate circular motion round a fixed axis. CRANK; PARALLEL MOTION; STEAM ENGINE.

Drums and band-wheels are contrivances by means of which motion is communicated from one shaft, revolving on its axis, to another able also to revolve in a parallel direction, and either in the same or in opposite directions, through the interposition of straps of leather, gutta-percha, or elastic web. The advantage of this method of transmitting power is, that directly the resistance to be overcome exceeds the adhesion of the strap upon the band-wheel, the former slips, and is unable to produce motion; whereas when toothed wheels are used, if the resistance should be suddenly increased, there is a danger of producing a rupture, or at least a serious derangement, of the machinery. On the contrary, there is often a practical inconvenience in the use of straps, from the extension of the materials of which they are composed; and it is not therefore customary to resort to their use in heavy or important machinery. When it is desired to change the direction of

motion of the shafts, the bands are crossed; and it is essential that, wherever it is possible so to do, the faces of the wheels should present slightly convex surfaces, in order to keep the bands steady. Band wheels, equally with toothed wheels, admit of an infinite variety of velocity combinations, of which the speed pulleys of the turning lathe may be cited as characteristic illustrations. Among practical men, the first motion band wheel is usually called the *drum*, and the second wheel is called the *pulley*; and the pulleys, where more than one are used, may either be fixed or loose, and made to work, by means of ratchets or of clutches, in any way that may be required.

Clutches, or the other varieties of loose coupling gearing, are used for the purpose of connecting or disconnecting parts of a machine when it may be desired to start its motion at will, or to arrest the same; whilst boxed couplings, or fixed connections, are used when the respective parts are intended to revolve continuously. The fast and loose pulley, the friction clutch, and the conical friction and reversing gear, have been introduced in order to obviate the danger which attends the abrupt connection of moving gear with portions of a machine in repose; but in spite of the inconvenience arising from this cause, and of the danger of stripping the teeth of cog-wheels when suddenly connected, through the inertia of the materials themselves, it is almost constantly the practice to allow the follower to fall upon and to fit into, the driver by means of a series of projections and recesses. Clutches or couplings should be placed as near to bearings or plummer blocks as possible, in order to secure the greatest possible amount of rigidity in the portions of the shafts connected.

After all, the most satisfactory way of explaining the construction of machinery is to refer to the best examples of the means of superseding the necessity for mere brute or manual labour; and a description, such as may be found in Warr's 'Dynamics,' of the recently invented turning-lathes, planing, punching, boring, drilling, screwing, and wheel-cutting machines, of the Nasmyth's hammer [HAMMER, POWER AND STEAM], and of the 'Times' printing machinery, will therefore teach the general reader far more of the power, the advantages, and the details of those various important inventions than any abstract remarks on the principles connected with them could do. The technical reader would also find it advisable to refer to special treatises on these subjects rather than to confine himself to general remarks; and he is therefore referred, in addition to the works already mentioned, to 'Buchanan on Mill-work,' new edition by G. Rennie; Coriolis, 'Mécanique des solides,' &c.; Hachette, 'Traité des Machines'; Borgnis, 'Traité des Machines'; and the various works which treat of the application of the power of the ordinary prime movers, such as steam, water, wind, horse, or man's power. [MOVING POWER.] Much information on these subjects is also to be obtained from the 'Mechanic's Magazine,' the 'Transactions of the Society of Arts,' the 'Engineer,' and from Armangaud's 'Publication Industrielle des Machines,' &c., &c.

MACHINES, CALCULATING. Before computers had attained great proficiency in performing arithmetical operations by the pen, machines by which the results of such operations could be obtained by inspection were in almost constant use. The Roman abacus [ABACUS] continued to be employed in the south of Europe till the end of the 15th century, and in England to a later period. An account of the prismatic rods invented by Napier for the performance of arithmetical operations is given under NAPIER'S BONES; and the nature and use of the logarithmic scales, under SLIDING RULE.

The celebrated Pascal constructed, it is said, when only nineteen years of age, a machine for executing the ordinary operations of arithmetic. It was an assemblage of wheels and cylinders. On the convex surfaces of the latter were the numbers with which the operations were to be performed: these operations consisted chiefly in the addition and subtraction of sums of money having the denominations of livres, sous, and deniers, for which may be substituted pounds, shillings, and pence; and to those denominations the numbers were adapted. Extending round the convex surface of the first cylinder on the right hand of the machine, and one above the other, were the two series,

0, 11, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1
11, 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10;

the first of which served for the subtraction and the other for the addition of pence; the cylinder being turned in the same direction for both operations. Upon the surface of the next cylinder on the left were the two series,

0, 19, 18, 17, 16 1
19, 0, 1, 2, 3 18;

serving for the like operations on shillings: and on the left of this last were several cylinders, about each of which were the two series—

0, 9, 8, 7, 6, 5, 4, 3, 2, 1
9, 0, 1, 2, 3, 4, 5, 6, 7, 8;

and these were used for operations with pounds, or with any numbers in the decimal scale. Attached to the axles of the first cylinder was a wheel having on its circumference 12 teeth; on that of the second, one having 20 teeth; and on the axle of each of the other cylinders was a wheel having 10 teeth. Before an operation commenced, the

zeros of the numbers in the first or second series above, on all the wheels, were brought by hand to the front of the machine. As an example of the method of using the machine, let it be required to add together the following sums of money:—

£8 9s. 8d.
4 15 6

By means of a pointer the wheel connected with the first cylinder on the right is to be turned till the eighth tooth, and under it the number 8 on that cylinder, are brought to the front; in like manner the number 9 on the second cylinder and 8 on the third are brought to the front: thus the series of numbers in the fronts of all the cylinders exhibits the first of the above sums of money. Then, by means of the pointer, the first wheel and cylinder on the right hand are to be turned till the sixth tooth (after the eighth) comes to the front, when the cylinder having, from its first position, performed on its axle one revolution and $\frac{2}{12}$ of another, the number 2, representing $12 + 2$, or

1s. 2d., appears in front. Now, by the construction of the wheel-work, one complete revolution of the first wheel and cylinder on the right hand causes the wheel and cylinder on its left to turn one-twentieth part of a revolution; by which means, in this example, the number 9 being already in front of the latter cylinder, the number 10 is now there; thus the one shilling obtained by the addition is, as it were, carried. The second wheel and cylinder being now turned by means of the pointer till the fifteenth tooth, after the tenth, is brought to the front, the number in front of the cylinder below is 5, representing $20 + 5$, the cylinder having made $1 + \frac{5}{20}$ revolutions from its first position; there is thus obtained 1l. 5s. One revolution of the second wheel and cylinder causes the next, towards the left, to make one-tenth of a revolution; and thus the 1l. is carried, so that the number in front of the third cylinder is now 9 instead of 8. This third wheel and cylinder are next turned by means of the pointer till the fourth tooth, after the ninth, is brought to the front, when there appears on the cylinder below it the number 3, representing $10 + 3$; and the next cylinder on the left, in front of which was previously zero, has now 1, which may thus be said to have been carried. The subtractions are performed exactly in the same manner as the additions, by means of the numbers in the upper series on the cylinders.

Subsequently to the time of Pascal, Leibnitz invented a machine by which arithmetical computations could be made: but no account of it appears to have been published.

The most extraordinary calculating machine ever contrived is that of Mr. Babbage, which has had an eventful history. In 1822 Mr. Babbage read two papers before the Astronomical Society, descriptive of a machine which he had devised, for working mathematical questions of some complexity, and even printing its own results by means of types. An application was made to the government for pecuniary aid, in applying the machine to the construction of mathematical tables; and in 1823 the government sought the opinion of the Royal Society on the merits of the machine. A committee almost unexampled in scientific strength met to examine the question; it comprised the names of Davy, Herschel, Young, Wollaston, Pond, Kater, Brande, Baily, Brunel, Colby, and Davies Gilbert; and the highly favourable report sent in by this committee led the government to promise pecuniary aid, in a matter intended wholly for public benefit, and not for the inventor's emolument. Unfortunately, the arrangement was badly organised, and has given satisfaction to no one. The plan of the machine underwent changes, the drawings prepared were very elaborate, and artisans had to be specially educated to the work. By the year 1828, a sum of 3000l. had been advanced by the government; parliament complained, and the government complained, because no machine was yet forthcoming. A second committee of the Royal Society made a report, countenancing a further application of public money to this purpose. A sum of 3000l. more was advanced, and then 600l., in 1829; besides a large expenditure out of the private purse of Mr. Babbage himself. In 1830 a third committee investigated the subject, at the request of the government; and the report of this committee led to a further advance of funds, not only for making the machine itself, but also for building a house to contain it. When 17,000l. had been spent, an irreconcilable dispute took place between the government and Mr. Babbage; no further money was given; and the operations were suspended. Mr. Babbage developed a new plan by which his machine would perform higher mathematical problems; his first he called a *difference engine*; the second would, if ever completed, be an *analytical engine*; but no funds being forthcoming, the operations were never resumed. In 1843 the government placed the difference engine, so far as it had been constructed, in the museum of King's College, London; and there it remains to the present time (1860), an unfinished memento of a splendid conception. The machine is barely a yard in height, by half a yard in width and a foot in depth; and it certainly appears surprising that no greater result than this has been presented for so enormous a sum of money.

So far as it is possible, we shall now describe the principle and action of Babbage's difference engine in a brief form: treating it as if

the machine were finished and at work according to the inventor's plan.

In any series of numbers arranged in line or column, if the difference between the first and second, between the second and third, and so on, be taken, there will be formed a line or column of what are called first differences: if the difference between the first and second, between the second and third, and so on, of these last numbers be taken, there will be formed a line or column of what are called second differences. Proceeding in like manner to form third, fourth, &c. orders of differences, there will at length be found a series of differences which are either constant, or to a great extent are very nearly so. Thus, taking the series of numbers in the column N below, the several orders of differences will be as in the succeeding columns; the numbers in the sixth column being constant:

N	Δ^1	Δ^2	Δ^3	Δ^4	Δ^5
243	781				
1024	2101	1320			
3125	4651	2550	1230		
7776	9031	4830	1830	600	
16807	15961	6930	2550	720	120
32768					
&c.	&c.	&c.	&c.	&c.	&c.

Now it is evident that, having any one of the numbers in the first column, and the numbers corresponding to it in the several columns of differences; all the succeeding numbers of the series may be found by mere additions. It may happen however that while the numbers in the original series increase, the numbers in some of the columns of difference may decrease; and then, in forming the terms of the series, subtractions might take place: in such a case, the arithmetical complements of the numbers to be subtracted being taken, the operations may still be performed by additions only.

Babbage's Difference Engine accomplishes these additions by the movements of a number of cylinders having on the convex surface of each the series of numbers 1, 2, 3, 4, 5, 6, 7, 8, 9, 0. The operations are thus distributed: by the first, the additions are made; and by the second, there is introduced the 1 which should be carried to the *ten's* place every time that the sum of two numbers is greater than 10. Let it be imagined that there are several vertical axes, on each of which are several cylinders one above another; and that these axes with their cylinders are capable of being turned by wheelwork, so that any one of the ten figures may be made to stand on the face of the machine, and immediately under a fixed index. Let it be further imagined that, when the moving power (the hand of the operator applied to a winch) has made one quarter of a revolution, the first, third, fifth, &c., axes may turn, causing the cylinders on them to make parts of a revolution or allowing them to remain at rest as the case may be, while all the cylinders on the second, fourth, &c., axes remain at rest. Again, when the moving power has made the second quarter of a revolution, let it be imagined that certain, only, of the cylinders on the first, third, fifth, &c. axes make one-tenth of a revolution, so that, whatever figure be under the index of each of these moving cylinders, the next figure, in increasing order, may be brought under that index; the cylinders on the second, fourth, &c., axes still remaining at rest. Let it next be imagined that, when the moving power describes the third quarter of a revolution, the cylinders on the second, fourth, &c., axes describe parts of a revolution or remain at rest, the cylinders on the other axes being unmoved: and lastly, when the moving power has described the fourth quarter of a revolution, let certain cylinders only on the second, fourth, &c., axes make one-tenth of a revolution, the other cylinders remaining at rest. Then it may be understood that by the first and third of these motions, numbers are added together: while, by the second and fourth, 1 is carried to each figure which ought to be increased in consequence of a sum of two figures being greater than 10.

As an example, let it be required to obtain the numbers of the series in the first column above, beginning with 3125. The figures composing the numbers are brought under the indices in front of the cylinders on the first vertical axis, towards the left hand; and the figures composing the several orders of differences in front of the

N	Δ^1	Δ^2	Δ^3	Δ^4	Δ^5
3	4	2	1	0	0
1	6	5	8	6	1
2	5	5	3	0	2
5	1	0	0	0	0

cylinders on the other axis, towards the right, as in this second table. Then the moving power being turned one quarter of a revolution, each cylinder in the first, third, and fifth vertical columns will be turned through as many tenths of a revolution as are expressed by the number in front of the cylinder immediately on its right hand: thus, the cylinder having 3 in front (at the top of the first vertical column) will move through four-tenths of a revolution, and the number 7 will be brought under its index in front. The cylinder having 1 in front (in the first vertical column) will be turned through six-tenths of a revolution, which will bring 7 under its index in front;

and so on. The numbers in front of the whole machine will now stand thus:—

N	Δ^i	Δ^{ii}	Δ^{iii}	Δ^{iv}	Δ^v
7	4	3	1	0	0
7	6	3	8	7	1
7	5	8	3	2	2
6	1	0	0	0	0

By the addition (in the preceding table) of 5 in the third column to 8 in the fourth, there should be produced 13, whereas 3 only appears under the index of the cylinder (in the third column of the present table), therefore 1 must be *carried*. The operation of carrying is performed by the action of the moving power in the second quadrant of its revolution; and, in the present example, this does nothing more than turn the cylinder marked 3 (in the first line, third column) through one-tenth of a revolution, which brings 4 to the front of that cylinder. The reader may now imagine the 3 to be effaced, and the number 4 introduced in its place. Now the moving power turning through the third quarter of a revolution, the cylinders on the second and fourth axes are made to turn through as many tenths of a revolution as are expressed by the figures on the cylinders immediately on their right hand. Thus, the cylinder marked 4 in the column of the last table will turn through four-tenths, and this movement will bring to its front the number 8; the cylinder marked 6 will be turned through three-tenths of a revolution, which will bring to its front the figure 9; and so on. The numbers in front of the machine will now stand thus:—

N	Δ^i	Δ^{ii}	Δ^{iii}	Δ^{iv}	Δ^v
7	8	4	1	0	0
7	9	3	5	7	1
7	3	8	5	2	2
6	1	0	0	0	0

The moving power turning through the fourth quadrant will perform the operations of carrying; and, in the present example, the cylinder marked 9 will turn one-tenth, which brings 0 (for 10) to its front; this causes another carrying, and the cylinder marked 8, in the same column, will turn one-tenth; which brings 9 to its front. The cylinder marked 1 in the fourth column will turn one-tenth on account of the carrying from the cylinder 5 below it, which brings 2 to its front; and the machine will stand thus:—

N	Δ^i	Δ^{ii}	Δ^{iii}	Δ^{iv}	Δ^v
7	9	4	2	0	0
7	0	3	5	7	1
7	3	8	5	2	2
6	1	0	0	0	0

The operation is now completed: the number succeeding 8125 in the series is 7776; and the like operations being performed with the instrument in the present state, the next number will be obtained in the first column. It has been supposed that the instrument has only six axes carrying cylinders; but it is evident that, if a number consisting of more than four places of figures were given, or were to be produced, a greater number of axes would be necessary.

In a limited space, we can do no more than give the following general notion of the mechanism by which these remarkable movements are produced. Immediately behind each column of the cylinders

carrying the figures and in a vertical plane perpendicular to the front of the machine, is a vertical axle *x* which carries, opposite to each cylinder, two horizontal wheels *A* and *B*, and between them a moveable bolt *c*, also in a horizontal position. These two wheels are

capable of being connected with or disconnected from the axle, so that they may or may not turn with the latter. The upper wheel *A* is furnished with teeth, standing out horizontally from the rim, and these work in the like teeth formed about the cylinder *D* carrying the figures so that the wheel *A*, when it turns with its axle, may be said to drive the cylinder. It is also furnished with teeth which are perpendicular to its lower surface, in the manner of an inverted crown wheel. The bolt *c*, which is under this wheel, and passes through the axle, is capable of being moved a short distance horizontally; it is provided, near its extremity, with a pin or tooth *a* standing perpendicularly above its upper surface, and with a pin *b* perpendicularly below its inferior surface. And the lower wheel *B* carries a wedge or inclined plane *c*. Behind the wheels on the axle *x* is another axle *y*, which is also in a vertical position; this carries a projecting bar or finger *m* which revolves horizontally when the axle is made to turn by the action of the moving power. During its revolution it meets, at a proper place, one extremity of a lever *n* which is capable of turning on a pivot at *p*: that extremity being displaced, the extremity of the opposite arm presses against the end of the bolt *c* in the axis *x* and causes the upper pin *a* to enter between two teeth of the crown-wheel *A*. This wheel is thus fixed to its axle so as to be compelled to turn with the bolt; and the horizontal teeth of the wheel, consequently, cause the cylinder *D* carrying the figures to turn on its proper axis *z*. Such is the nature of the mechanism that, while the moving power describes the first and third quadrants of its revolution, the cylinder *D* might make a complete revolution; but, in general, the cylinder is to make only as many tenths of a revolution as are expressed by the figure in front of the next cylinder on its right hand; and therefore the bolt is to be withdrawn from the crown-wheel when such part of a revolution has been performed. This is accomplished by the pin *b*, which, moving along the wedge or inclined plane *c*, draws the bolt back so that the pin *a* above is removed from between the teeth of the crown-wheel; the latter is thus disengaged from its axle and ceases to revolve: at the same time the cylinder *D*, with which it is connected by the horizontal teeth, ceases also to revolve. The cylinder remains then at rest till it is moved at a subsequent step in the process. If the cylinder is not to turn while the moving power describes the first and third quadrants, an apparatus provided for the purpose removes out of its place the lever which should press against the end of the bolt. For every vertical axis carrying cylinders in front of the machine, there is an axle carrying wheels and bolts, and an axle carrying the fingers which lock the bolts: and behind every cylinder is its proper apparatus, consisting of wheels, bolt, and finger.

The process of *carrying*, which takes place when the moving power is describing the second and fourth quadrants of its revolution, is accomplished thus:—A bar or finger revolves on the axle of the lowest cylinder *D*, for example, in the first vertical column on the left; and, at a proper time comes against the extremity of a claw which then engages itself between the teeth of a ratchet-wheel connected with the next cylinder above it: both the wheel and cylinder are thus made to turn, but the length and position of the claw are such that the cylinder can only make one-tenth of a revolution, and thus bring to the front a figure greater by unity than that which was there before. When a cylinder has made the movement just indicated, a projecting pin, called a thumb, on the axle of the lower cylinder, touches a trigger which raises, out of a notch in the claw, a hook which retained the latter: a spiral spring then draws back the claw and allows it to fall between the next teeth of the ratchet-wheel without creating any movement in the cylinder; and the apparatus is thus prepared for the next carrying operation which is to take place.

It was proposed by the inventor to apply to the machine an apparatus by which the numbers obtained from the cylinders in the left-hand column might be immediately transferred, by the operation of *punching*, to plates of copper, in order that the results given by the machine might be printed without a possibility of error. To effect this, a curvilinear bar of metal was to act on an arm of a lever so as to raise it to ten different heights corresponding to the ten figures on the surface of a cylinder; and the opposite arm of the lever was to move an arch carrying ten punches having on them the characters 1, 2, 3, &c. in relief. The plate of copper being below, a bent lever was to press the punch upon the plate, and produce the impression of the figure. The different figures in front of the first column of cylinders would thus be successively transferred to the copper-plate; and the arch and plate being shifted, the set of figures brought in front of the cylinders in the same column, at the next operation with the machine, would be transferred in like manner.

If Mr. Babbage's plan had ever been fully carried out, the machine would perform the several operations of simple arithmetic on any numbers whatever. It would combine the quantities algebraically or arithmetically in an unlimited variety of relations. It would use algebraic signs according to their proper laws, and develop the consequences of those laws. It would arbitrarily substitute any formula for any other, effacing the first from the columns on which it is represented and making the second appear in its stead. It would effect processes of differentiation and integration on functions in which the operations take place by successive steps. The inventor further asserts that the engine would be particularly fitted for the operations of the combinatory analysis, for computing the numbers of Bernoulli, &c.

This machine embodies the principles of all the calculating machines yet proposed. A few words concerning other contrivances may, however, be desirable.

Staffel's arithmetical machine is about 18 inches in length, 9 in breadth, and 4 in height. It contains three rows of small cylinders, thirteen in the first row, and seven in each of the others; upon each cylinder are ten numerals, from 0 to 9. These cylinders act upon each other by means of small wheels, levers, sliders, and other delicate apparatus. The upper surface of the machine presents seven small holes, with moveable plates beneath them, marked by numerals, seven similar holes over the peripheries of seven little vertical wheels, and thirteen number-holes in a distinct row. Each set of seven holes has a traversing movement, but the longer row is immovable. Every one of the twenty-seven holes has ten numerals, from 0 to 9, belonging to it. In performing any sum, the conditions of the question are arranged on the two smaller rows; and then, by turning a handle, the result makes its appearance at the holes of the larger row. By different modes of adjusting the two smaller rows of holes, and of turning the handle, the machine performs addition, subtraction, multiplication, division, and evolution. It can multiply seven digits by seven, or millions by millions. A very beautiful part of the apparatus is a little bell, which rings whenever the operator attempts to perform an impossible operation, such as subtracting a larger number from a smaller, or dividing a smaller by a larger; the machine refuses to work, rings a bell, and stops.

Colmar's arithmometer is rather larger than Staffel's machine. It has as many slides, each working in a groove, as there are digits in the quantity which it is capable of calculating; and each groove is numbered with ten figures, from 0 to 9. There are as many round holes in a brass plate as there are possible places of figures in the result to be produced; and beneath each hole may appear any one of the ten numerals. The machine is adjusted to any particular problem or sum in addition, subtraction, multiplication, division, or evolution, by moving some among the many slides; these slides work upon certain wheels and levers underneath, which cause the proper figures for the result to make their appearance at the row of holes in the brass plate.

Wertheimer's machine, for the addition and subtraction of numbers and moneys, consists of a box having a metal plate divided into nine indexes, with semicircular notches, under which are placed a series of holes. Numerals are engraved round the indexes. The semicircular notches are furnished with teeth, with a pointer to insert between them, for the purpose of bringing the notch opposite to any particular figure.

Baranowski's Ready Reckoner is intended for the calculation of wages, prices, interest, and other sums of money. If it be to calculate the amount of wages at a given rate, the weekly rate, printed on paper, is brought to view in an opening in a brass plate, by means of a handle; a slide is withdrawn belonging to the particular number of days for which the calculation is made, another for any extra hours, and another for any odd quarters of an hour; and the printed figures revealed by the moving of these slides give the sum total of wages.

Schott's calculating machine can perform addition only. Lalanne's calculating-rule is a peculiar apparatus for solving the problems usually worked by the sliding-rule. Dr. Roget's sliding-scale of involution is like the apparatus just noticed, and bears more resemblance to the ordinary sliding scale than to a calculating machine. Maurel's calculating machine is something like Colmar's, founded mainly on the action of graduated slides. Roth's automaton calculator, and Slovinski's calculating machine, are two other examples mainly dependent on the same principle. Maurel's calculating machine works, like Colmar's, through the medium of graduated slides.

The most important calculating machine ever invented (next to Babbage's), and decidedly the most important ever actually finished, is Scheutz's. It presents another example of ingenuity ill rewarded. In 1834, after reading an account of Babbage's machine as at that time proposed, M. Scheutz, a technologist at Stockholm, conceived the idea of something to the same end on a different principle. Under SCHEUTZ, GEORGE, and EDWARD, in the BIOGRAPHICAL DIVISION of this work, will be found a narrative of the circumstances connected with the invention and the difficulties which attended the construction of this machine, as well as some particulars respecting its principle, and the share taken by Mr. Babbage, the inventor of the first calculating machine, in directing the attention of the scientific men of this country to its value. The machine was exhibited in London in 1854, and in Paris in 1855; and in 1856 it was sold to the Dudley Observatory, at Albany, in the United States, at a price quite inadequate to the labour and thought bestowed upon it. Mr. Babbage deplored that the machine had not been secured for and by England; he greatly admired it, and attached high value to its power of computing mathematical tables. Not only can it do this, but it impresses each result on a piece of lead, from which a *cliché* cast in type-metal can be obtained, applicable to printing from. The machine, which is about the size of a square pianoforte, calculates to sixteen places of figures, and prints to eight. By taking out certain wheels and putting in others, the machine can be readily caused to produce and record its results in £ s. d.; in degrees, minutes, and seconds; in tons, cwts., and lbs.; or in any one among a large number of different modes. When once the machine is set with the conditions of the problem, a handle is turned, and the

results appear at the rate of 25 figures per minute, not merely calculated and recorded, but actually stamped or impressed upon a plate of lead. Mathematically speaking, this is a *difference* engine, like Babbage's, and depending on the same general principles, though worked out by means of original details.

A full and minute description by the inventors of the machinery of this remarkable instrument is given in the specification of the English patent, dated October 17, 1854.

MACLAURIN'S THEOREM. [TAYLOR'S THEOREM.]

MADDER, COLOURING MATTERS OF. The root of the madder plant [*RUBIA tinctorum*, in NAT. HIST. DIV.] is so extensively used for the preparation of all shades of purple, red, brown, and even black dyes, that in importance to the calico-printer and others, it is second to no other dye-stuff, except perhaps indigo.

Madder grows in the south of Europe, many parts of the Levant, and is largely cultivated in Holland. It does not contain the colouring matter ready formed, nor does the substance from which the colour is derived reside indiscriminately in all parts of the plant. It is indeed only the ligneous or woody portion of the long fibrous roots of the rubia that are valuable, and hence the various operations that are performed upon them before being sent into commerce. These preparatory processes consist in, first, carefully drying the roots in a stove, then thrashing with a flail, winnowing and sifting away the dust or dried cellular matter, and finally, again drying, and, in nearly all cases, powdering the resulting fibres.

The ground madder thus prepared is called in France *garance*, but occasionally it is sent out in the entire state, especially from Turkey and the Levant, and is then called *lizari* or *alizari* (from *ρίζα*, the modern Greek name for madder).

Madder thus prepared has a reddish appearance, and contains three distinct colouring principles, namely: 1. *Alizarin*; 2. *Purpurin*; and 3. *Rubiadin*. Of these, alizarin is the one of greatest importance. Madder also contains, 4. *Chlorogenin*—a green, pulverulent species of extractive matter; 5. *Erythrozym*, a ferment; and 6. *Rubian*, a body of deep yellow colour, not, however, a colouring principle in the practical sense of the term, but which, by the action of ferments, acids, or alkalis, yields up large quantities of alizarin.

1. *Alizarin* ($C_{22}H_{10}O_8 + 6HO$) *Lizarinic acid*. This substance, though chiefly resulting from the decomposition of rubian during the dyeing operations, has nevertheless been shown by Schunk to exist ready formed in dried madder, and has probably been produced from the rubian originally in the plant by the action of a ferment in the drying operations.

Alizarin was first discovered by Robiquet and Colin. It is identical with Runge's *Madder red*. It may be extracted directly from the root, but is best obtained from *garancin*, a substance prepared by acting upon powdered madder, with strong hot sulphuric acid, by which the earthy matter and a large quantity of valueless tissue is rendered soluble, and is removed by well washing the residue with water. The dried, insoluble portion constitutes the *garancin*; it is very largely used in print works, and it is from this that alizarin is most conveniently prepared. The *garancin* is boiled for some time with a quantity of water, and the colouring matters precipitated from the resulting liquor by sulphuric acid. The precipitate well washed with cold water, dried, and submitted to sublimation, yields beautiful orange coloured needles of alizarin. An impure alizarin was described by Robiquet and Colin, under the name of *colorin*.

Alizarin is tasteless and inodorous, neutral to test paper, almost insoluble in cold water, more so in hot water, and freely taken up by alcohol or ether. The alkalis dissolve it, forming a beautiful purple solution, but acids reprecipitate it unchanged. It forms a splendid red lake with alumina, and purple ones with lime, baryta, and oxide of iron. Alizarin is converted into phthalic acid (*alizaric acid*) by ebullition with dilute nitric acid, and since chloroxynaphthalic acid, a body prepared from naphthalin, also yields phthalic acid under the same circumstances, it has been thought, that chloroxynaphthalic acid is simply alizarin with an atom of hydrogen replaced by one of chlorine. Schunk, however, does not think this to be the case, nor has Strecker himself, who was the first to throw out the hint, been able to replace the chlorine in chloroxynaphthalic acid by hydrogen and thus convert it into alizarin. Were this accomplished, naphthalin would no longer be a waste product as it now is, but become of great value and importance.

Alizarin plays the principal, and probably the only part, in the production of madder colours. Schunk has, in fact, after a long course of experiments, been led to the conclusion, that the final result of dyeing with madder and its preparations is simply the combination of alizarin with the various mordants employed, and that consequently if an economical method of preparing alizarin on a large scale could be discovered, a great gain would result to the arts.

2. *Purpurin* was the name given by Robiquet and Colin to the colouring matter that remained dissolved in the alum liquor after the preparation of alizarin. Dr. Debus has called it *oxylizaric acid*. It dissolves in alkalis with a red colour, quite distinct from the purple of an alkaline solution of alizarin, and moreover the resulting solution decomposes when exposed to the air, which is not the case with a similar solution of alizarin. Professor Stokes, who has examined the optical properties of purpurin, also thinks it quite distinct from alizarin; nevertheless, these two bodies are shown, by other re-actions,

to be closely allied substances. Further research will probably remove all doubt concerning them.

3. *Rubiacin* ($C_{32}H_{11}O_{10}$). This body is one of several yellow colouring matters contained in madder. It was first noticed by Runge, who called it *Madder-orange*. Schunk has obtained it in acicular and lamellar crystals. It gives red compounds with bases, but does not contribute to the production of fast colours during the process of madder dyeing; Schunk thinks that it even acts injuriously. Persalts of iron convert it into *rubiacic acid* ($C_{32}H_9O_{17}$), a lemon yellow, non-crystalline powder. *Rubiicate of potash* crystallises from water in long, silky, brick-red needles.

Rubiacin is soluble in strong sulphuric acid, and hence is found in the acid liquor mentioned when treating of the preparation of alizarin.

4. *Chlorogenin*.—Kuhlman, by treating garancin with boiling alcohol, evaporating to dryness, dissolving in water, precipitating with acetate of lead and baryta water, and treating the precipitate with dilute sulphuric acid, isolated a body that he called *xanthin*. Schunk, however, shows that this body is a mixture of rubian and an extractive matter to which he has given the name *chlorogenin*, the *rubichloric acid* of Rochleder. Its aqueous solution becomes brown when exposed to the air, and hence the uniform dirty reddish-brown tint which a piece of calico exhibits after having been dyed with madder. In the manufacture of garancin, the chlorogenin is mostly decomposed and removed. The effect of adding lime to a dye-bath is partly, according to Schunk, to take away the chlorogenin, rubiacin, and other valueless and injurious bodies from their aluminous combination.

5. *Erythrozym* is the name given by Schunk to an azotised body existing in madder. It acts as a ferment, and bears the same relation to rubian that emulsin does to amygdalin. It is the ferment peculiar to madder, or rather to rubian, the latter body not yielding alizarin when brought in contact with other ferments. It contains very little more than 4 per cent. of nitrogen. It may be obtained from madder by digesting the latter in water at 100° Fahr., and precipitating the aqueous extract with alcohol.

6. *Rubian* ($C_{56}H_{34}O_{30}$). Madder is extracted with boiling water, the extract agitated with animal charcoal, and the latter digested in alcohol. A solution is thus obtained which leaves on evaporation a nearly pure substance, to which Schunk has given the name of *rubian*. It is an amorphous, gum-like mass, of deep yellow colour, intensely bitter taste, and soluble in water and alcohol. By the action of various agents it is broken up into grape sugar and alizarin, together with 7. *Rubiretin*, and 8. *Verantin*; the latter substance being accompanied by 9. *Rubiafin*, 10. *Rubiagin*, 11. *Rubianin*, and 12. *Rubiadin*, according to the reagent employed, as seen in the following table:—

By Ferments.	By Acids.	By Alkalies.
Alizarin.	Alizarin.	Alizarin.
Rubiretin.	Rubiretin.	Rubiretin.
Verantin.	Verantin.	Verantin.
Rubiafin.	Rubianin.	Rubiadin.
Rubiagin?		

7. *Rubiretin* ($C_{25}H_{12}O_8$), and 8. *Verantin* ($C_{25}H_{10}O_{10}$), are amorphous, resinous, and of brown colour. Along with alizarin they form the part insoluble in cold water when rubian is acted upon by either of the agents named. Rubiretin is easily soluble in alcohol: verantin less soluble in that liquid.

9. *Rubiafin* ($C_{32}H_{13}O_9$) accompanies the last-named bodies when the splitting up is effected by erythrozym. When treated with perchloride of iron it passes, like rubiacin, into rubiacic acid. It crystallises in yellow shining needles.

10. *Rubiagin* accompanies rubiafin. It seems to be a distinct substance, but Dr. Schunk has not yet obtained it in a state of purity.

11. *Rubianin* ($C_{44}H_{24}O_{20}$) accompanies alizarin, rubiretin, and verantin, when rubian is decomposed by acids. It is tolerably soluble in boiling water, and crystallises in lemon-yellow silky needles.

12. *Rubiadin* ($C_{32}H_{13}O_9$). This body is associated with the other three when rubian is acted upon by alkalies. It crystallises in beautiful golden-yellow scales, insoluble in water, soluble in alcohol, and is completely volatilised by heat.

13. *Chlororubian* ($C_{44}H_{27}ClO_{24}$). When exposed to the action of chlorine, rubian is converted into a crystallisable substance, called by Schunk *Chlororubian*. It is insoluble in water, but soluble in alcohol. It is formed from rubian by the elimination of one atom of sugar, and the replacement of an atom of hydrogen by one of chlorine. By the continued action of chlorine it is converted into *Perchlororubian* ($C_{44}H_9Cl_9O_{15}$). By the action of acids upon chlororubian a second atom of sugar is set free, and *Chlororubiadin* ($C_{32}H_{13}ClO_9$) is formed.

14. *Rubianic acid* ($C_{52}H_{29}O_{27}$). (*Ruberythric acid*, Rochleder.) This acid results from the action of alkalies and oxygen upon rubian; a vessel to which the air can have access being therefore used in its preparation. It gives definite crystalline compounds with the alkalies, is tolerably soluble in boiling water, and crystallises in lemon-yellow silky needles. By decomposition it yields one atom of alizarin, and two of grape sugar.

Madder-dyeing. The colouring matters of madder have but little

affinity for cotton fibre, but a great affinity for mordants; hence, when a pattern has been printed on cotton with a mordant [CALICO-PRINTING, col. 516], and the whole passed through the madder bath, it is not difficult to remove the colour from the un-mordanted portions, and thus secure a good white ground.

Madder colours are very stable, resisting the action of air and light in a remarkable degree. Turkey-red cloth is a well-known illustration of this fact.

From a consideration of the properties of the various substances contained in madder, Dr. Schunk is enabled to explain several curious phenomena observed in madder-dyeing which were not previously known. For instance, it is well known that the sudden heating of a madder-bath produces prejudicial effects. This no doubt arises from a stop being put to the action of the ferment (erythrozym), and the consequent non-production of the whole of the alizarin from the rubian. Hence, too, the advantage of mixing several sorts of madder together, some containing excess of rubian, some excess of ferment. Again, it is well known that up to a certain time madder improves by keeping; this, no doubt, is owing to the thus increased action of the ferment, an action that evidently commences so soon as the madder-roots are gathered from the soil.

MADHOUSE. [LUNATIC ASYLUMS.]

MADNESS. [INSANITY; LUNACY.]

MADRIGAL, in music, an unaccompanied vocal composition, sometimes in three parts, but commonly in more; and as the true madrigal is written in what is termed the learned style—abounding in points of the fugal or imitation kind—it is, almost necessarily, as much the produce of study as of genius. Morley—himself a renowned writer of madrigals—says that in this sort of composition “no point is to be long stayed upon, but once or twice driven through all the parts, and sometimes reverted [inverted], and so to the close, then taking another. And that kind of handling points is most esteemed when two parts go one way, and two another way, and most commonly in tenths or thirds. Likewise the more variety of points be showed, the more is the madrigal esteemed: and withal you must bring in fine bindings (sincopations) and strange closes, according as your ditty shall move you. Also in compositions of six parts (or five) you must have an especial care of causing your parts to give place one to another, which you cannot do without resting; nor can you cause them to rest till they have expressed that part of the ditty which they have begun.” (‘Treatise,’ 1597.)

The madrigal is to be traced to a very early period in the history of vocal music in parts: to the Flemings we are indebted for its birth, about the middle of the 16th century, and the Italians took it up shortly after, with what success the names of Palestrina, Marenzio, Conversi, Ferretti, &c., will bear witness. Nor were the English deficient in emulation or slow in manifesting it; Morley’s first book of madrigals was published in 1594, Weelkes’s in 1597, Wilbye’s in 1598, Bennet’s in 1599, and only a few years later, John Ward’s and Orlando Gibbons’s appeared. Dowland’s and Ford’s lovely compositions, the former published in 1597, and the later in 1607, have the title of madrigal bestowed on them, but they are more properly *part-songs*, or what would now be called *glees*. It is not too much to say, that the English madrigalists have no superiors, and that for the preservation of this high order of composition, the art has long been, and still continues to be, indebted to the Madrigal Society, a club, consisting chiefly of amateurs, founded in London in 1741, and which, by zeal and perseverance, has succeeded in diffusing throughout the British Isles a taste for a species of music as delightful as it is scientific, and exactly suited to the choral societies already existing, or springing up, in all our great manufacturing and commercial towns.

Every attempt to fix, with any precision, the derivation of this word, has been baffled. Menage thinks that *Mandra*, ‘a sheep-fold,’ is its source, for he supposes it to have been, in its origin, a pastoral song. Bishop Huet considers it a corruption of *Martegaux*, a name given to the inhabitants of a district of Provence, who, according to a learned French writer, excelled in the species of poetical composition called the *Madrigale*. Dr. Burney agrees with Doni, who derives it from *Alla Madre*, the first words of certain short hymns addressed to the Virgin, and afterwards to the mother of Love, *Madre galante*. And Sir John Hawkins remarks, that there is a town in Spain named Madrigal. But all these conjectures—for they amount to no more—are merely plausible, and we only offer them in the absence of a more satisfactory etymology.

The English glee [GLEE] is probably a graft of the madrigal. The finest madrigals belong to the 16th century; but the term *glee* does not seem to have been used before the middle of the 17th century, at which time a glee was defined as “a song of three or more parts upon a gay or merry subject, in which all the voices begin and end together, singing the same words.” It will be seen that the structure of the madrigal is much more complicated than this, although some of our glees might be appropriately termed madrigals.

MAGAZINE. Magazines are of two descriptions, permanent or temporary. Permanent magazines are strong buildings constructed generally of brick or stone within a fortified place, or in the neighbourhood of a military or naval station, in order to contain in security the gunpowder or other warlike stores which may be necessary for the defence of the place, or for the use of the troops who are to perform

military duty in the province or district. Temporary magazines are such as are constructed during a siege for the supply of the batteries, &c., or such as are hastily constructed in a fortress for expense magazines.

On account of the liability of gunpowder to become deteriorated by humidity and by variations in the state of the air, the buildings in which it is contained are constructed with every precaution necessary to ensure dryness, and, as nearly as possible, a uniformity of temperature within them. They are generally in places remote from other buildings; they are furnished with metallic conductors, in order to avert danger from lightning; and, for security against the attempts of ill-disposed persons, they are surrounded by a wall and ditch. When in situations where they may become the objects of hostile measures, they are made shell-proof.

A magazine within the walls of a fortress is usually formed on an esplanade; and, if small, it may be in the interior of some bastion remote from the front against which an attack of the enemy is likely to be directed. But it would be preferable that such buildings should be in some work beyond the main rampart of the place, that an accident may be attended with as little detriment as possible.

The powder required for the immediate service of the works on the front attacked is taken from the general magazine, and placed in what are called *expense magazines*; that is, in temporary bomb-proof buildings, or in casemates formed in the rampart along that front, from whence it is conveyed to the batteries. These casemates or *souterreins* should be as well ventilated as possible, by having doors and windows in the interior side of the rampart, and loop-holes or small perforations on the side next to the main ditch. They sometimes constitute the only bomb proofs belonging to a fortress; and then they become of the utmost importance, serving as well for the abode of the troops, when not on duty, as for the preservation of the powder and stores. [BOMB-PROOF; CASEMATE.] In such situations however, as magazines, they are subject to some disadvantages from which isolated buildings are free; for besides the humidity, which the means they possess for ventilation are not sufficient entirely to remove, the blowing up of any one by an accident would evidently destroy the rampart, and expose the place to the risk of an immediate assault. And when the vault springs from the back of the wall which constitutes the exterior revêtement of the rampart on any face of the work, its lateral pressure would facilitate the formation of a breach by overturning the wall as soon as the latter became weakened by the fire from the enemy's battering artillery.

The dimensions of magazines are necessarily dependent on the quantity of powder which they may be required to contain. Vauban, in his 'Traité sur la Défense des Places,' speaking of such as are made in the ramparts of fortresses, recommends them to be from 8 to 12 feet wide, with semicircular-headed vaults; and he proposes that the barrels of powder should be placed in them in two rows, with a passage from 3 to 4 feet wide along the middle. The great magazines which have been constructed in this country consist of several parallel vaults, separated from each other by brick partition-walls, in which are doorways for affording lateral communication. Each vault is about 90 feet long and 19 feet wide internally, and it has a door at each extremity. The side walls are from 8 to 10 feet thick, and are strengthened by buttresses built at intervals against them. The concave or interior surface of each vault, in a vertical and transverse section, is nearly of a parabolical figure, above the springing courses; and the exterior surface has the form of two inclined planes meeting in a longitudinal ridge-line above the middle of the vault. The thickness of the brickwork forming the vaulted roof is therefore various; at the crown it is 7 or 8 feet, and on the hances about 3 feet, this being considered sufficient to resist the shock of falling shells. The vault, on the exterior of the inclined planes, is covered with flat tiles, slates, or, still better, asphalt; and the gutter between every two roofs with sheet-lead or copper. The height interiorly, from the level of the floor to the crown of the arch, is 19 feet; and the lines at which the vaulting springs from the side walls are at half that distance above the floor. The narrow vertical perforations which are made through the side and end walls, for the purpose of giving air to the interior, are cut so as to leave a solid block or traverse of the brickwork in the middle of the thickness of the wall; the line of the perforation branching laterally from its general direction, and passing along the two sides of the traverse. By this construction, while air is admitted, no object capable of doing mischief can be thrown in from the exterior of the building. The flooring-planks are, of course, laid on joists raised considerably above the ground. One vault, of the dimensions above given, would contain 2500 barrels, or 225,000 lbs. of powder.

When the roof of a magazine is covered with earth to the height of several feet, for the purpose of securing it effectually against the effect of falling shells, the rain-water absorbed by the earth may at length penetrate through the brickwork to the interior of the building. In order to prevent this effect it has been proposed that the roof should be covered with common hollow tiles, having their concave surfaces upwards, and that, over these, boards should be laid to carry the earth. The absorbed water would thus drain off in the channels formed by the tiles, and be conveyed away by the gutters between the roofs.

Temporary magazines, such as are formed to supply the batteries in

a siege, are necessarily made of wood. They are of three descriptions, the rectangular, the lean-to, and the triangular.

The lean-to magazine, which was the one principally employed by the British army in the Peninsula for field powder magazines, is formed by laying stout timbers, generally termed splinter-proof timber, at an angle of 45°, sloping towards the fortress, against an earthen parapet (revêted interiorly), so as to enclose a space of which the section is nearly a right-angled triangle. The splinter-proof timbers are then covered with earth; from its great inclination this face is well able to resist the effects of vertical fire or shells falling on it, while the powder is protected in front by the parapet from the effects of shells fired horizontally. This form of magazine, however, is very ill adapted for stowage.

The triangular field powder magazine, the section of which is an isosceles right-angled triangle, is also bad for stowage, and takes long to construct. It may, however, be placed in a traverse or parapet. The size as adopted at Chatham was 15 feet 6 inches in length of body of magazine, 6 feet 6 inches wide at bottom, and 6 feet 6 inches high in the clear; or, with the length increased to 18 feet to allow of a low passage, 2 feet 6 inches wide and 4 feet 6 inches high, leading perpendicularly from one end of the magazine to the rear. The interior form of the magazine is preserved by five triangular frames of carpentry, with sheet planks and fascines in front. The body of the magazine may be sunk 4 feet.

The rectangular field powder magazine, which is the one now generally adopted in the British service, consists of a rectangular excavation 12 feet 3 inches long by 6 feet 3 inches wide, with a passage at right angles to its length at the end of one side, running to the rear. The sides are formed by rectangular frames 4 feet 9 inches high and 4 feet 4 inches wide from out to out; behind these, to support the earth, sheeting planks 1½ inches thick are placed. Over the top, supported at each end by the frames, are splinter-proof timbers about 6 inches in width by 9 inches in depth, the whole being covered with earth to the thickness of about 5 feet. The sheeting is not carried along the whole of both sides, but stops short of one frame, which is the entrance from the passage, the passage being formed something like the gallery of a mine; the frames of the passage are only 2 feet 2 inches wide. There are then four body-frames, two on each side, opposite to one another, and four passage-frames, two in the body of the magazine, opposite to one another, and two more for the continuation of the passage to the rear. The tops of the frames are on the level of the ground, the magazine being sunk below that level; and a small ditch, which supplies earth for cover, surrounds the magazine, leaving a parapet of about 4 feet in breadth all round it. This is the best description of field magazine, especially for stowage.

MAGELLANIC CLOUDS. [NEBULÆ.]

MAGI, the name of the priests among the Medes and Persians, whose religious doctrines and ceremonies are explained under ZOROASTER, in BIOG. DIV. The Magi formed one of the six tribes into which the Medes were originally divided (Herodot. i. 101); but on the downfall of the Median empire they continued to retain at the court of their conquerors a great degree of power and authority. It would appear however that they did not witness with indifference the sovereignty pass from the Medes to the Persians; and it was probably owing to the intrigues of the whole order that a conspiracy was formed to deprive Cambyses of the throne by representing one of their order as Smerdis, the son of Cyrus, who had been previously put to death by his brother. Herodotus, who has given the history of this conspiracy at length, evidently regarded it as a plot on the part of the Magi to restore the sovereignty to the Medes, since he represents Cambyses on his death-bed as conjuring the Persians to prevent the Medes from obtaining the supremacy again (Herodot., iii. 65); and the Persians themselves must have looked upon it in the same light, since after the discovery of the conspiracy, and the murder of the pretended Smerdis by Darius Hystaspes and his companions, a general massacre of the Magi ensued; the memory of which event was annually preserved by a festival, called the "Slaughter of the Magi" (*Μαγοφόνια*), in which none of the Magi were allowed to appear in public. (Herodot., iii. 79; Ctesias, 'Pers.' c. 15.) This event does not appear to have much impaired their influence and authority, for they are represented by Herodotus, in his description of the Persian religion, as the only recognised ministers of the national religion (i. 132).

The learning of the Magi was connected with astrology and enchantment, in which they were so celebrated that their name was applied to all orders of magicians and enchanters. Thus the Septuagint translates the Chaldee *אֲשָׁר*, "enchanter," by the word *Magus*, *μάγος*. (Dan., i. 20; ii. 2, 27; compare Acts, xiii. 6, 8.) The word was also applied to designate any men celebrated for wisdom; whence the wise men of the East who came to see Christ are called simply Magi. (Matt., ii. 1, 7, 16.)

It would appear from a passage in Jeremiah (xxxix. 3), that the Babylonian priests were also called Magi, if at least the interpretation of *Rab-Mag* (*רַב־מַג*) "chief of the Magi," be correct. (Gesenius, 'Hebrew Lexicon,' under *מַג*.)

The etymology of this word is doubtful. In Persian the name for priest is *mugh*; and it is not improbable, as Gesenius has conjectured, that the word may be connected with the root meaning *great*, which we

have in the Greek *μέγας*, the Latin *magis* and *mag-nus*, the Persian *mih*, and the Sanskrit *mah-at*. It is a curious fact that the Hindu grammarians derive *mah-at* from a verb *mah*, signifying "to worship."

(Wilson's *Sanskrit Dictionary*, under *mah-at*.)

MAGIC LANTERN is a species of lucernal microscope, its object being to obtain an enlarged representation of figures, on a screen in a darkened room, by means of the pencils of light issuing from a lamp or candle and passing through a convex lens.

The instrument consists of a lantern, generally of tin, and of a cubical form, in the interior of which is the light; and at a perforation in one of the sides is applied a tube projecting horizontally from it. Immediately before the aperture, and within the tube, is a glass lens, often nearly a hemisphere and three or four inches in diameter, serving to condense the light which proceeds from the lamp both directly and by reflexion from a concave mirror attached to the side of the lantern which is directly opposite the aperture: this tube carries within it another, which is also provided with a convex lens, and is capable of a small movement for the purpose of adjustment.

A groove in front of the lantern and parallel to that front receives a rectangular frame containing the glass plates on which are painted, with transparent colours, the objects of which an enlarged view is to be obtained. Instead of a single convex lens, the sliding tube is sometimes provided with two such lenses; these are placed at a short distance from one another, and have between them a perforated plate of tin, or diaphragm, crossing the interior of the tube, for the purpose of cutting off the more divergent rays which would render the figures indistinct. The lens, or pair of lenses, is of such a focal length that the rays in each of the pencils which proceed from the object may unite on the screen in what is called the *conjugate focus*, and thus produce the enlarged representation of the figure.

Several figures are usually drawn on the same plate of glass, and the plate is capable of being moved by hand in the groove so that the different figures may be brought successively before the spectator: for the purpose of heightening the effect, motions can be given to the figures by means of a simple wheel-work.

The magic lantern is said to have been invented by Kircher, in the 17th century; it is described by him in his '*Ars Magna Lucis et Umbræ*.' Cellini, however, who died in 1570, describes some magical effects, such as spectres in the midst of ascending smoke, &c., which are easily produced by the magic lantern, so that Kircher, who was not born until the year 1601, was but a re-inventor, or perhaps only a describer of an instrument, the possessors of which would be likely to keep it secret as far as possible. The celebrated Euler proposed to substitute for the lens of the lantern a concave mirror, perforated in the middle like that of a Gregorian telescope: this was to be placed in the interior of the lantern with its polished surface towards the light and its convexity towards the object. The light was to be so disposed that none of it should pass directly through the aperture in front of the lantern so as to fall on the screen; and that which was reflected from the concave mirror, after falling upon one with a plane surface, was from thence to be reflected in a contrary direction upon the object. The rays in the pencils proceeding from the object were to pass through a lens in the tube, as in the former construction; and, by converging with greater accuracy to points on the screen, they would have produced a more correct image than that which results from refracted light alone.

The magic lantern must have been at best an imperfect affair until the invention of the Argand lamp, by Ami Argand in 1789, by which a clean, clear, bright flame was for the first time produced in lamps. It was not, however, until 1802, that any decided improvement was made, and then M. Philipsthal exhibited at the Lyceum in London the form of instrument known as the *Phantasmagoria*. The lantern itself was similar to but larger than that which served for more general purposes; and the sliding tube which carried the farthest lens had a greater range of motion. The objects to be exhibited were painted upon a glass plate, with this remarkable difference from former attempts, namely, that all the parts not occupied by the figure, were covered with an opaque varnish, so that no light could pass except through the figure, which was thus rendered more brilliant. The machine was placed upon a stage capable of being moved on wheels in a direction perpendicular to the screen on which the objects were represented. The screen was a curtain made of fine muslin or gauze, and covered with varnish so as to be quite transparent: it was stretched in a vertical position across the theatre or apartment; and this being made quite dark, the spectators occupied the space in front of the screen, while the apparatus was disposed on the opposite side.

In any magic lantern when the tube carrying the lens which is farthest from the lamp is drawn out as much as possible, the magnitude of the image represented on a screen is the smallest; the image increases in magnitude in proportion as the tubes are diminished in length, or as the lens is brought nearer to the body of the lantern. It increases also in proportion as the whole machine is made to recede from the screen; and the variations of the length of the tubes must, by the exhibitor, be combined with the different distances of the lantern from the screen, in order that by the just convergence of the rays in each pencil, on the screen, the proper degree of distinctness of vision may be obtained under all the variations in the magnitude of the image. The consequence of this is the very serious defect that

when the image is smallest, and apparently farthest off, it is brightest, and when large, and apparently near, the light is comparatively faint from being spread over a larger surface. This is partially remedied by intercepting a portion of the light, when the image is small and bright, by means of a gauze screen: an ingenious *artificial iris* has also been contrived for the purpose.

Care is taken that during the exhibition all light shall be excluded both before and behind the screen, except that which, in proceeding from the lantern, produces the image to be observed; and the screen being itself invisible, the spectators can scarcely divest themselves of the idea that they are looking into a dark cavern, in which the objects, at first dimly visible as specks in its deepest recesses, appear to be gradually advancing towards them, increasing in magnitude as they seem to approach; after the objects have been some time apparently in the immediate presence of the company, perhaps surrounded by a blaze of light, they seem as gradually to retire, and at length they vanish, leaving the place in profound darkness.

Several of these particulars are derived from a 'Treatise on the Magic Lantern,' written in 1854 by Mr. Tomlinson, and published by a maker of the instrument for the benefit of his customers. This treatise lets us into the secret of many of the effects which always excite the admiration, if not the wonder, of the spectators. The following, for example, is the introduction to a description of *dissolving views*:—

"Dissolving views are produced by means of two magic lanterns of the same dimensions and optical power. They are placed on the same table or horizontal plane, with their lens-tubes inclined towards each other in such a way as to produce a single disc of light upon the opposite wall or screen, instead of two discs, which would be formed if the lens-tubes were parallel. Now it is evident that if by the conjoint action of these two lanterns a disc of light be formed on the screen, the dark shutter of either lantern may be let down, without destroying such disc, but only depriving it of half its light. Suppose, further, that each lantern contained a slider, one representing the exterior of a building, and the other representing the interior, if both lanterns were acting on the screen at the same time, the super-position of images would produce a confusion which the eye could not unravel; but if the dark shutter were let down, so as to intercept the light of one lantern, the other would act with full effect. While the spectators are enjoying one view, the shutter of the other lantern is raised, and that of the first is gradually let down; and it is during this process of moving the shutters that the dissolving effect takes place, because a portion of the light from both lanterns falls upon the screen at the same time; but the moment one shutter is quite down and the other fully raised the dissolving effect ceases. There is one effect which usually excites a great deal of surprise among the spectators—namely, the view of the interior of a large building, deserted and solitary, and while the spectator is gazing, the same building becomes filled with people; this is produced by painting the same building on two sliders of precisely the same dimensions, and with all the same details in both cases, only in one case empty and in the other full of people; or as it is not necessary to repeat any part of the painting, one slider may have the building only, and the other the people on a ground of the deepest shade used in the former slide. While the lantern containing the slider representing the empty building is acting on the screen, the shutter of the other lantern is slowly raised, and that of the first as slowly lowered. Thus without any necessary dissolving effect, since the two sliders represent the same object, the empty building appears gradually to fill with people. In the same way a leafless tree covered with snow, may quickly put on the verdure of summer."

In the following passage the means of producing some of the effects before referred to are described:—

"Many beautiful effects are produced by allowing both lanterns to act together; one lantern being first employed to produce an effect, and the other being used to heighten it, or to produce some new feature. Thus, for example, a rainbow may be made to appear in the sky of a landscape, as represented by one lantern. For this purpose the landscape without the rainbow is shown by one lantern, and a slider containing only a rainbow, or a sky and a rainbow, being placed in the second lantern, the shade is removed from it, and the landscape is enlivened by this beautiful addition. By means of a second slider, lightning may also be represented, but in such case the effects of the flash are due to two glasses, both blackened, and containing the same flash of lightning, one of which is fixed and the other moveable. The latter is moved rapidly so as to allow the flash to be seen for an instant and then shaded from view. The dancing of the *aurora borealis* is produced in a similar way. The whirling of smoke issuing from a volcano is produced by a painting set in a circular brass frame, and capable of revolving round and round by means of a little cog-wheel fitting into the teeth of a circular rack. On turning a handle which projects from the side of the slider, the cog-wheel is made to revolve, and this gives motion to the ring of teeth to which the painting is attached. In this way the smoke appears to whirl out of the crater of the volcano, and to be dissipated by the wind. An effect which produces great surprise is that of falling snow. This is managed by a piece of black silk perforated with holes formed into a roll, mounted in a mahogany frame, and used as a slider, as the paintings are. By means of a small projecting handle at the side the silk can be wound upon another roller,

and in its passage will present the effect of falling snow. The landscape exhibited by the other lantern is a winter scene: but before the snow slider is called into action, darkness is made to come over the landscape by means of a piece of black crape held over the aperture. As the lantern inverts the images, and the sliders are put in with what may be called the wrong side up, so by winding the silk from the bottom roller on to the top one, the ascending holes appear to form a descending shower on the screen."

MAGIC SQUARE. This term is applied to a set of numbers arranged in a square in such a manner that the vertical, horizontal, and diagonal columns shall give the same sums. Such arrangements were known very early to the Hindus, Egyptians, and Chinese, among whom, as also among the Europeans of the middle ages, a belief existed that such squares had astrological and divinatory qualities. Emanuel Moschopolus,* of Constantinople, wrote on them in Greek in the middle of the 15th century. Others who have written on the subject are Leibnitz, Frenicle, Bachet, La Hire, Saurin, &c. (See Montucla's 'History,' vol. i., p. 346; 'Encyclopédie Méth.' article 'Quarrés magiques'; Hutton's 'Dictionary'; and the 'Mathematical Recreations' of the same author.)

Though the question of magic squares be in itself of no use, yet it belongs to a class of problems which call into action a beneficial species of investigation. Without laying down any rules for their construction, we shall content ourselves with destroying their magic quality, and showing that the non-existence of such squares would be much more surprising than their existence.

Take any set of numbers in arithmetical progression, and such that their number shall be a square number, say the first sixteen numbers—

1	2	3	4	5	6	7	8
16	15	14	13	12	11	10	9

any of these in the first half, with its corresponding number in the second half, makes up 17. Write the numbers in the following manner:—

1	2	3	4
5	6	7	8
9	10	11	12
13	14	15	16

Take four of these in such a manner as to take one out of each row, and one out of each column, and it will be found, and may easily be proved, that the sum of numbers in every such set must consist of two pairs of corresponding numbers, so that their sum must be twice 17, or 34. The different ways in which this can be done are in number $4 \times 3 \times 2 \times 1$, or 24, as follows.—

1 6 11 16	5 2 11 16	9 2 7 16	13 2 7 12
1 6 15 12	5 2 15 12	9 2 15 8	13 2 11 8
1 10 7 16	5 10 3 16	9 6 3 16	13 6 3 12
1 10 8 15	5 10 15 4	9 6 15 4	13 6 11 4
1 14 7 12	5 14 3 12	9 14 7 4	13 10 7 4
1 14 11 8	5 14 11 4	9 14 3 8	13 10 3 8

Out of these subdivisions a set may be taken from each, so that no number shall be repeated, in 24 different ways, as in the following sample, which shows the four ways that begin with 1 6 11 16.—

1 6 11 6	1 6 11 16	1 6 11 16	1 6 11 16
5 2 15 12	5 2 15 12	5 10 15 4	5 14 3 12
9 14 7 4	9 14 3 8	9 14 3 8	9 2 15 8
13 10 3 8	13 10 7 4	13 2 7 12	13 10 7 4

Now in each of these 24 squares, every horizontal row can be written in 24 orders [COMBINATIONS], and in putting the different orders together, each square admits of $24 \times 24 \times 24 \times 24$, or 331,776 arrangements, without altering the horizontal rows, but only the order of the figures in each row. But the order of the horizontal rows can be varied 24 ways in each square, and there are 24 squares; so that we have $331,776 \times 24 \times 24$, or 191,102,976 squares, no one of which repeats any number more than once, and in every one of which the sum of any horizontal row is 34, made by two pairs of numbers which give 17 each. But the number of ways of forming 34 out of four of the first sixteen numbers is not yet exhausted: for, taking any one set, say

1	16	11	6
---	----	----	---

in which 1 and 6 correspond to 16 and 11, we may write 2 and 5, or 3 and 4, for 1 and 6, so that we have not included in the preceding list

2	16	11	5
3	16	11	4

with all their variations of order; and similar ones for all the rest of the list. It would be almost impossible to doubt that in many of this enormous number of squares, the vertical columns will sometimes be cases of these new sets: and it would be something short of magic if some should not also have diagonal columns which fulfil the same condition. In fact, Frenicle has shown 880 methods of making these squares

* Some think this work was written by Emanuel Moschopolus the elder, a Cretan, who lived at the end of the 13th century.

magical, a few of which are as follows ('Divers Ouvrages, &c. Paris 1693):—

1 16 11 6	4 11 14 5	13 4 5 12	16 3 10 5
13 4 7 10	6 13 12 3	16 6 11 1	8 2 13 11
8 9 14 3	9 2 7 16	3 9 8 14	9 15 4 6
12 5 2 15	15 8 1 10	2 15 10 7	1 14 7 12
8 12 5 9	8 10 3 13	8 12 5 9	10 11 5 8
11 1 16 6	15 1 12 6	10 1 16 7	15 2 16 1
13 7 10 4	9 7 14 4	13 6 11 4	6 7 9 12
2 14 3 15	2 16 5 11	3 15 2 14	3 14 4 13

In Frenicle's list of 880, only those squares are included which are essentially different: thus the following four, which may be made by turning the last square into different positions, count only as one.

10 11 5 8	8 1 12 13	13 4 14 3	3 6 15 10
15 2 16 1	5 16 9 4	12 9 7 6	14 7 2 11
6 7 9 12	11 2 7 14	1 16 2 15	4 9 16 5
3 14 4 13	10 15 6 3	8 5 11 10	13 12 1 8

The methods which have been given for the formation of magic squares are divided into different rules, according as the number in each side is odd, evenly even, or oddly even. A general method which shall apply to all cases is yet wanting. For a full account of these rules see Hutton's 'Mathematical Recreations.'

MAGISTRY. The term used by alchemists to denote precipitation of metallic solutions by water; thus, the basic nitrate of bismuth, precipitated on diluting the neutral nitrate, was termed magistry of bismuth.

MAGISTRY OF BISMUTH. [BISMUTH, *Mononitrate of.*]

MAGISTRAL. Roasted copper pyrites employed in the extraction of mercury from its ores by amalgamation.

MAGISTRATE, a word derived from the Latin *magistratus*, which contains the same element as *magnus* and *magister*, and signifies both a person and an office. A Roman magistratus is defined to be one who presides in a court and declares the law, that is, a judge. The kings of Rome were probably the sole magistratus originally, and on their expulsion the two consuls were the magistratus. In course of time other offices, as those of Prætor and Ædile, were created; and those who filled these offices were elected in the forms prescribed by the constitution, and they had jurisdiction. [JURISDICTION.] The original notion of a magistratus, then, is one who is elected to an office, and has jurisdiction.

In England the term magistrate is usually applied to justices of the peace in the country, and to those called police or stipendiary magistrates, such as there are in London. It has also been applied in other ways; for instance, people have sometimes said that the sovereign is the chief magistrate in the state. But these applications of the term do not agree with its proper sense.

MAGNA CHARTA. The terms of the compact between the feudal chief and his dependants underwent frequent changes in the middle ages, the consequence for the most part of resistance made by the tenants, and struggles to regain liberties which had been originally surrendered or taken from them by the force and power of the chief. When a material alteration was made in the terms of the compact, a record was made of it in writing. These records are called charters, in the restricted use of a term which is popularly applied to almost every species of early diplomas. The tenants of the various honours, or great tenancies in capite, are seldom without one or more charters which have been granted to them by their lords, by which exemptions or privileges are given, base services are commuted for payments in money, and the mode is settled in which justice shall be administered among them. And even in some of the inferior manors there are charters of a similar kind by which certain liberties are guaranteed by the lord to his tenants. These charters run in the form of letters, "Omnibus," &c., from the person granting; they set forth the thing granted, and end with the names of persons who were present when the lord's seal was affixed, often ten, twelve, or more, with the date of place and time of the grant.

Such a charter is that called the Magna Charta granted by King John, but acting in his twofold character of the lord of a body of feudatories, and the sovereign of the realm. This charter is often regarded as the constitutional basis of English liberties, but in many of its provisions it seems to have been only a declaration of rights which had been enjoyed in England before the Conquest, and which are said to have been granted by King Henry I. on his accession. However, if it did not properly found the liberties which the English nation enjoys, or if it were not the original of those privileges and franchises which the barons (or the chief tenants of the crown, for the names are here equivalent), ecclesiastical persons, citizens, burgesses, and merchants, enjoy, it recalled into existence, it defined, it settled them, it formed in its written state a document to which appeal might be made, under whose protection any person who had any interest in it might find shelter, and which served, as if it were a portion of the common law of the land, to guide the judges to the decisions they pronounced in all questions between the king and any portion of the people.

Beside the great charter there was granted at the same time a charter

relating to the forests only. There were very extensive tracts of land in England which were actually forests, uncultivated, and reserved for the pleasure of the king; and there were purlicues to these forests, all of which were subject to a peculiar system of law, many parts of which were felt to be oppressive, and from some of which this charter exempted the people.

The independence and rights of the church were also secured by the great charter.

Magna Charta has been printed in a great variety of forms; there are fac-similes of a copy of it which was made at the time, and still exists in the British Museum, and of another preserved at Lincoln, and translations of it into the English language. It is thus so easily accessible, that it will not be expected that we shall give a copy of it, or even a complete abstract of its multifarious provisions, some of which are completely obsolete, and the terms obscure.

Such a concession from the king was not gained without a violent struggle; in fact he was compelled to yield it by an armed force, consisting of a very large portion of the baronage, which he was far too feeble to resist with effect. The names of the chiefs are preserved by the chroniclers of the time, and in the charter itself; and whenever recited, they call up to this day a mingled feeling of respect and gratitude, the respect and gratitude which men pay to those who have obtained for them the extension of political privileges, though it may appear that those privileges were nothing more than rights of which they had been deprived, and to which therefore they may be said to have been justly entitled. They appear the patriots of a rude age, and the mists of distance and antiquity obscure to us the selfishness and the other evils (if such existed) which were manifested in the contest. The first name is that of Robert Fitz-Walter, who belonged to the great family of Clare. The title given to him as head of the host was Marshal of the Army of God and of the Holy Church. Next to him come Eustace de Vesci, Richard de Percy, Robert de Roos, Peter de Brus, Nicholas de Stuteville, Saier de Quenci, earl of Winchester, the earls of Clare, Essex, and Norfolk, William de Mowbray, Robert de Vere, Fulk Fitz Warine, William de Montacute, William de Beauchamp, and many others of families long after famous in English history, the progenitors of the ancient baronial houses of England.

The charter was signed, or rather sealed, not in any house, but in the open field, at a place called Runnymede, between Windsor and Staines; but it was not merely by an accidental meeting of two armies at that place that this act was done there, for it appears by Matthew of Westminster that Runnymede was a place where treaties concerning the peace of the kingdom had been often made. All was done with great solemnity. The memorable day was June 5, 1215.

What was unwillingly granted, it could scarcely be expected would be religiously observed. John himself would gladly have infringed or broken it, as would his son King Henry III., but the barons were watchful of their own privileges, those of the church, the cities, the boroughs, and of the people at large; and King Henry was led to make one or more solemn ratifications of the charter. To keep the rights thus guaranteed fully in the eyes of the people a copy was sent to every cathedral church, and read publicly twice a year.

See the work of Sir William Blackstone, entitled 'The Great Charter and Charter of the Forest (on Public Wrongs), with other authentic Instruments; to which is prefixed an Introductory Discourse concerning the History of the Charters,' Oxford, 1759, 4to. He wrote also an express treatise on this charter. An exact fac-simile has been engraved and published of the charter, from a copy preserved in the archives of the cathedral church of Lincoln, with other of the greater charters. In the first volume of 'The Statutes of the Realm,' published by the Board of Commissioners on the Public Records, these charters are all printed, with English translations of them.

MAGNESIA. [MAGNESIUM.]

MAGNESIA, MEDICAL PROPERTIES OF. Oxide of magnesium, termed also, from the mode of procuring it, calcined magnesia, or magnesia usta, is an alkaline earth possessing the usual qualities of alkalis in their habitudes with acids, and likewise the peculiar property of exciting generally purgative action of the intestines. This last-mentioned power gives it a distinctive character among alkaline remedies, as it can be employed not merely to counteract acidity, but also to remove the exciting cause when that consists in the presence of crude or undigested acid-yielding materials in the stomach. Its action as a purgative seems mainly to depend upon its meeting with acids in the stomach, and so forming soluble salts. When these are not present the magnesia remains undissolved, and if used repeatedly may accumulate in the intestines, and, becoming agglutinated by the mucous secretions, give rise to much uneasiness. Hence some other aperient should from time to time be given. [ANTACIDS.] When however acidity exists, either along with constipation or diarrhoea, more particularly in children, from the milk disagreeing, or from a diet unsuited to their delicate organs of digestion being forced upon them, magnesia is a very proper medicine, especially as it appears to possess a specific power of diminishing gastrointestinal irritation. (Hufeland, quoted in Pereira's 'Materia Medica.') It is generally expedient to add rhubarb to it, and combine it with some carminative. In such a state of combination it is peculiarly useful in what is termed diarrhoea crapulosa, arising from too great a mixture or too large a quantity of food.

Where it is determined to use magnesia, and sufficient acid does not exist in the stomach to ensure the formation of a soluble salt, a little lemon-juice may be added to it. The subcarbonate of magnesia has nearly the same action as the calcined magnesia, but when it meets with acids in the stomach effervescence takes place, accompanied with a disengagement of carbonic acid gas, which in some cases is inconvenient, in other instances extremely beneficial. In some almost uncontrollable irritations of the stomach, where food and medicines are alike rejected, subcarbonate of magnesia will be retained, and, by allaying the irritability, allow other remedies to be subsequently employed. Both the subcarbonate and the calcined magnesia are much used to correct heartburn, and to check the lithic acid diathesis; but their employment requires much judgment and attention [ANTACIDS; ANTALKALIES], as persisting too long in the employment of this or any alkaline preparation brings on a phosphatic condition.

Sulphate of Magnesia, or Epsom salts, in the ordinary form, as met with in the shops, are small acicular crystals. This renders them liable to be confounded with those of oxalic acid; to avoid which the sulphate may be dissolved, and by recrystallisation they are obtained in large four-sided prisms, or four-sided pyramids. The taste of sulphate of magnesia is bitter and very unpleasant; but this is very much lessened by large dilution in water, which at the same time increases the purgative action of the salt, or by adding magnesia, or by giving it in compound infusion of roses and adding a few drops of dilute sulphuric acid, which augments the refrigerating property of the medicine. The addition of a little common salt to a solution of sulphate of magnesia increases its cathartic powers.

No saline medicine is so extensively employed as the sulphate of magnesia as a purgative; it is more rarely used as a diuretic or diaphoretic. Its action as a purgative is in general mild and certain, causing a considerable evacuation of the serous secretions of the intestines, and so producing a cooling or lowering effect. At the commencement of most inflammatory complaints and of fevers its employment is most beneficial. Its utility is often much increased by adding to the solution a very minute portion of tartarised antimony, so as to form the emetico-cathartic solution, which is found very serviceable in the fevers of India, and in those of the summer and autumn of European countries.

Small doses of sulphate of magnesia in bitter infusions are valuable in the treatment of dyspepsia accompanied with constipation. Many of the saline mineral waters resorted to for the cure of indigestion are chiefly indebted to the sulphate of magnesia for their purgative properties.

Sulphate of magnesia is a convenient antidote in cases of poisoning by the salts of lead or baryta. The saccharate of magnesia is an eligible form of exhibiting magnesia to children.

Magnesian limestone is sometimes employed for building, and is a very durable stone: it is however one of the most deleterious stones for masons to hew, as the gritty particles very speedily occasion disorders of the lungs, followed by early death. The mouth and nostrils of the workman should therefore always be defended by wearing a gauze mask.

MAGNESIUM (Mg). This metal was first obtained by Sir Humphry Davy, but its oxide or *magnesia*, and carbonate, or *magnesia alba*, have been known since the commencement of the last century. Its compounds are frequently met with in the inorganic kingdom, but are not so abundant as those of lime.

Magnesium may be obtained from its chloride by heating with potassium or sodium, or by subjecting the same salt to a voltaic current obtained by means of a few cells of a Bunsen's battery. Deville and Caron give the following details for the reduction of the metal. Six parts of chloride of magnesium are well mixed with one part of a fused and powdered mixture of chloride of potassium and sodium, one part of pure fluoride of calcium, and one of sodium in small pieces. The mixture is transferred to a red-hot earthen crucible, fitted with a lid. After some time the reaction takes place, and when the hissing noise has ceased, the lid of the crucible is removed, and the mixture stirred with an iron rod until the whole appears uniformly mixed, and the upper portion of the liquid mass is clear. The crucible is then removed from the fire, and when the saline mass is nearly solidifying, it is to be stirred with an iron rod so as to collect the suspended particles of metal. When cold, the mass is broken up, and the globules of crude magnesium picked out.

The metal thus obtained may be purified by placing it in a carbon tray, and heating it to whiteness in a carbon tube, a current of hydrogen being at the same time passed over it; it is subsequently remelted with chloride of magnesium, chloride of sodium, and fluoride of calcium.

If, in the above process, the current of hydrogen is rapid, the vapour of the magnesium is to a certain extent carried out of the tube, and on being ignited, burns with an exceedingly beautiful flame.

Magnesium is a metal of silvery white colour, and semi-crystalline or fibrous fracture. It fuses and volatilises at about the same temperature as zinc, to which metal it in many other points bears a very close analogy. It is malleable and ductile, may be easily polished, readily filed, and yields well to the chisel. Its specific gravity is 1.75. It does not tarnish in dry air, and in a damp atmosphere oxidises but slowly. This metal takes fire at about the temperature at which glass

melts, and burns with a steady and most brilliant flame. Could a cheaper process be discovered for the manufacture of magnesium, thin wires of it spun into a wick might no doubt be advantageously used in many instances as a source of light. Magnesium crystallises in octohedra. It acts but very slightly upon cold water, and is not rapidly oxidised by hot water. It ignites when brought into contact with hydrochloric acid; sulphuric acid dissolves it slowly with evolution of hydrogen.

The equivalent of magnesium is 12.

Magnesium and oxygen form only the following oxide:—

Magnesia, calcined magnesia, or oxide of magnesium (MgO). Prepared by heating the carbonate to full red heat. Its density depends upon that of the carbonate employed; if a light variety has been used, then *light* calcined magnesia results, but if a heavy carbonate, then *heavy* calcined magnesia is obtained.

Magnesia is a white powder, very voluminous, inodorous, and tasteless. In the oxyhydrogen blowpipe flame it fuses to a hard opaque enamel. Moistened with water it acts upon test paper like an alkali. Magnesia is a powerful base, forming salts with the acids that are usually very stable.

Hydrate of magnesia (MgO, HO) is precipitated in a semi-gelatinous state when an alkali is added to an aqueous solution of a salt of magnesia. It also occurs native. [MAGNESIA, in NAT. HIST. DIV.]

Iodide of magnesium (MgI). Magnesia dissolves in aqueous hydriodic acid, forming a difficultly crystallisable salt. On exposure to heat, it gives off hydriodic acid, and magnesia is left.

Bromide of magnesium (MgBr) may be prepared in the same manner as the iodide, than which it is far more stable. This salt is also found in sea water, and in many salt springs.

Magnesium and chlorine form

Chloride of magnesium (MgCl). Magnesia dissolves in hydrochloric acid, forming chloride of magnesium, but this solution cannot be evaporated to dryness without undergoing decomposition, unless chloride of ammonium is present, when a stable double salt is formed. This salt loses its chloride of ammonium when heated to redness, and the fused chloride of magnesium may then be poured out on to a slab. Thus obtained, it forms a white crystalline semi-translucent solid, very deliquescent, very soluble in water, and tolerably so in alcohol. It quickly decomposes in contact with air, and must therefore be kept in well closed bottles.

Carbonate of magnesia (MgO, CO_2), occurs native in acicular crystals. [MAGNESITE, in NAT. HIST. DIV.] It is also deposited in small prismatic crystals, containing three equivalents of water of crystallisation, when a solution of magnesia in carbonic acid is allowed to evaporate spontaneously.

Magnesia alba, the common magnesia of the shops, is a mixture of carbonate and hydrate of magnesia ($\text{MgO}, \text{CO}_2 + \text{MgO}, \text{HO}$) in very variable proportions, the carbonate however nearly always preponderating. It is made by mixing together solutions of sulphate of magnesia and carbonate of soda, the latter being in excess, collecting, well washing, and drying the precipitate. It is an exceedingly light powder, inodorous, and almost tasteless. Its density varies according to the strength of the solutions employed, being greatest when the two salts are mixed together, without the addition of water, fused in their water of crystallisation, evaporated to dryness, and the sulphate of soda subsequently washed out. The *heavy carbonate* thus produced is, however, liable to be semi-crystalline, or *gritty*.

Bicarbonate of magnesia ($\text{MgO}, 2\text{CO}_2$). This salt exists only in solution, and is made by passing carbonic acid through water in which carbonate of magnesia is suspended.

Sulphate of magnesia ($\text{MgO}, \text{SO}_3 + 7\text{HO}$). This salt was originally obtained in 1697, from the Epsom waters, by Dr. Grew, and hence its common name of *Epsom salts*. It occurs in sea-water, and in many mineral waters, and is largely prepared from *bittern*, or the mother liquor from which common salt has crystallised after sea-water has been evaporated; the first crystallisation is called *single epsoms*, and when recrystallised is denominated *doubles*. The principal source, however, of sulphate of magnesia is *dolomite*, or *magnesian limestone*, a double carbonate of lime and magnesia. [MAGNESIAN LIMESTONE, in NAT. HIST. DIV.] Chippings of this stone may be readily procured, as it is in very common use for building purposes, and on acting upon it with sulphuric acid, the carbonic acid is evolved, sulphates of lime and magnesia are formed, and the latter is separated from the former by simple solution in water, sulphate of magnesia being very soluble, while sulphate of lime is almost insoluble. On evaporating the solution, the sulphate of magnesia crystallises out. When prepared in this way, however, it frequently contains sulphate of iron, but this may, if necessary, be got rid of by calcining the salt. The sulphate of iron is then decomposed, peroxide of iron remaining while the sulphate of magnesia is unaltered, and may be dissolved away from the oxide of iron by water.

On evaporating and slowly cooling a solution of sulphate of magnesia, large four-sided rhombic prisms are obtained, but by rapid cooling and frequent agitation small acicular crystals are deposited, forming the *Epsom salts* as met with in pharmacy.

Sulphate of magnesia is colourless, transparent, and inodorous, but has an extremely bitter taste. Heated, it fuses, parts with its water of crystallisation, and finally becomes anhydrous. The crystals slowly

effloresce in very dry air. Five parts dissolve in four of water at 66° Fahr., and in still less of boiling water. Sulphate of magnesia is also exceedingly soluble in hydrochloric acid, but insoluble in alcohol.

Nitrate of magnesia ($\text{MgO}, \text{NO}_3 + 6\text{HO}$). Formed by dissolving carbonate of magnesia in nitric acid, and concentrating by evaporation. It then crystallises out in rhombic prisms and needles, very deliquescent, very soluble in water, and soluble also in nine times their weight of alcohol. They are almost insoluble in absolute alcohol.

Phosphate of magnesia and ammonia ($2\text{MgO}, \text{NH}_3\text{O}, \text{PO}_3 + 12\text{HO}$). Precipitated in a granular form, when phosphate of soda is added to a solution of magnesia in chloride of ammonium, containing also ammonia. By heat it is converted into bibasic phosphate, or pyrophosphate, containing 36.67 per cent. of magnesia.

Silicates of magnesia. Many of these occur native. See STEATITE, MEERSCHAUM, and HORNBLÉNDE, in NAT. HIST. DIV.]

Citrate of magnesia ($3\text{MgO}, \text{C}_3\text{H}_5\text{O}_7, \text{HO}$). Prepared by saturating citric acid with carbonate of magnesia. It is less bitter than most of the magnesian salts.

Effervescent citrate of magnesia, or granular citrate, as it is sometimes called, is nothing more than a mixture of bicarbonate of soda and tartaric acid, with a small but variable quantity of sulphate of magnesia: sometimes it contains a little citric acid. It is made by well mixing the ingredients, slightly moistening till the mass begins to swell from disengagement of carbonic acid, and then rapidly drying over a water-bath with constant stirring.

Double salts of magnesia, especially with alkaline salts, are very numerous.

Tests for magnesia. Magnesia is characterised by its not being precipitated from solution by hydrosulphate or carbonate of ammonia in the presence of chloride of ammonium, and by a granular precipitate with phosphate of soda and with arseniate of ammonia, especially if free ammonia is present.

Estimation of magnesia. This is generally effected in the state of bibasic phosphate ($2\text{MgO}, \text{PO}_3$), in the manner already mentioned under phosphate of magnesia.

MAGNET. The *natural magnet, loadstone, or lodestone*, is known in mineralogy as *magnetic iron ore*. It consists of one equivalent of protoxide and one equivalent of sesquioxide of iron ($\text{FeO}, \text{Fe}_2\text{O}_3$), and possesses the remarkable property of attracting iron and some other metals. It is said to have been found abundantly near Magnesia in Lydia, from which circumstance its name may have been derived from the Greek *μάγνης*. The attracting power of the magnet was known at a very early period, as references are made to it by Aristotle, and more particularly by Pliny, who states that ignorant people called it *ferrum vivum*, or quick-iron. The same author appears to have been acquainted with the power of the magnet to communicate properties similar to its own to other bodies.

The universal law, that re-action is co-existent with action, implies, that iron must re-act on the magnet, and we find in fact, that if a piece of iron be fixed, and a small magnet be suspended by an untwisted line near it, the magnet will then be moved towards the iron; thus all the iron in the mass of the globe acts upon a magnet. It is also known that electrical currents influence magnetic bodies [ELECTRO-MAGNETISM] while heat has an influence on magnetic intensity. Hence it follows as a mechanical consequence, that if a magnetic needle or cylinder be suspended by its centre of gravity, so as to be free to move in any direction round that point, it will not take an arbitrary position like unmagnetised bodies, but must take a specific direction, namely, that which represents the resultant of all the magnetic forces to which it is subject. Its position in a given place can be defined by two angles, the one called the *variation* or *declination*, the other the *inclination* or *dip*. The first is the angle formed by the vertical plane in which the needle lies with the plane of the meridian; the second is the inclination of the line of the needle to the plane of the horizon. The latter is avoided in the compass-needle by sustaining it horizontally on a point which is necessarily different from its centre of gravity, and the variation is then the angle made by the direction of the needle with that of an exact and horizontal north-and-south line. This property of the needle is called its *polarity*, and is a consequence of its other properties above noticed; the fact, however, escaped the notice of the Greeks and Romans of antiquity, but the Chinese appear to have been acquainted with it from a very remote date. The Chinese name it, according to its most valuable property, *ichu-chy*, or the "directing stone." In Tonkin it is called the "stone which shows the south." In Swedish it is *segel-sten*, or the "seeing stone;" in Icelandic, *leiderstein*, or the "leading stone," after the Saxon *lædan*, "to lead," whence the English *lodestone*. In a similar way is derived the term *lode-star*, or "guiding star," as applied to the pole-star, and the term *lode*, the "leading vein," in a mine. Polarity is the most useful of the known properties of the magnet, being of the most essential importance to the mariner, when the magnet is constructed in the form of the compass-needle. [COMPASS, HISTORY OF THE.]

Dr. Gilbert, who was physician in ordinary to Queen Elizabeth, states that P. Venetus brought a compass from China in 1260. Gilbert bestowed much attention on the subject of magnetism, and to some extent inculcated the doctrine of gravitation, by comparing the earth to a great magnet. His theory on this subject is given in a work

entitled 'Tractatus sive Physiologia nova de Magnete' (1600), and the term "poles of a magnet" arose from that theory, which is remarkably consonant with the notions of the present day: for the north pole of the magnet he denominated the south pole, in connection with his theory, while Poisson, in his elegant 'Memoirs on Magnetism,' calls the magnetic fluid at that extremity of the magnet the *austral fluid*, because, as like electricities repel [ELECTRICITY], so, on his hypothesis of the magnetic fluids, that occupying the north end of a magnetised needle is repelled by the boreal fluid of terrestrial magnetism.

The application of the compass to the purposes of navigation must speedily have led to the discovery of its variation, and in the 'Life of Columbus,' written by his son, it is distinctly assigned to that celebrated man; and though its amount in 1492 must have been small in France, Spain, &c., yet it was doubtless a very observable quantity in many of the regions visited by Columbus. Some have carried back the date of this discovery to the year 1269, but on very doubtful grounds. When its amount came to be observed with some accuracy, we find it at Paris, in 1541, $7\frac{1}{2}^{\circ}$ E.; in 1550, $8\frac{1}{2}^{\circ}$ E.; in 1580, $11\frac{1}{2}^{\circ}$ E.; in 1630, $4\frac{1}{2}^{\circ}$ E.; and at Rome, in 1670, 2° W. The following table shows the variation at London in different years:—

	East declin.	Zero.	West declin.
Years	1580, 1622.	1660.	1692, 1730, 1765, 1818, 1850.
Declination	$11^{\circ} 15' 6''$	0°	$6^{\circ} 13' 20'' 24' 41' 22' 80''$

[DECLINATION OF THE MAGNETIC NEEDLE.]

It is not improbable that Columbus was acquainted also with the diurnal variation, but nothing very accurate on this subject was known before the numerous and valuable observations made by Canton, in 1750. He showed that the needle vibrates, during the day and the night, through an arc as great as $13\frac{1}{2}'$ in the midsummer, the minimum $7'$ occurring in the winter season; he ascribed the diurnal variation to the action of solar heat affecting the intensity of the magnetism of the earth. The principles of thermo-electric currents were at that period unknown; but Hooke, in 1684, showed that iron and steel rods could be magnetised by rapidly heating and cooling them in the magnetic meridian. Graham, instrument-maker, of London, was the first who distinctly announced the diurnal variation, in 1772; the maximum declination being then $14^{\circ} 35'$ west. The variation of the variation was first observed by Gunter, in Brog. Div.]

The *dip* was first observed by Robert Norman in 1576. His mode of adjusting the compass-needle led him to this discovery; for he accurately balanced the needle on its pivot previous to magnetising it. After it became a magnet it would no longer balance on the same point, without attaching a small weight at the south extremity. When freely suspended by the centre of gravity, the north extremity became depressed, the dip then being about $71^{\circ} 50'$. The dip undergoes diurnal variations, as well as the declination; but observations on the former are far the most difficult. The dip also changes by elevating the needle to considerable heights, on which subject Biot has made some very delicate experiments. A very simple law relative to the amount of the dip at different parts of the earth's surface was remarked by Professor Kraft, of St. Petersburg, in 1809; namely, if we measure the latitude from the magnetic equator, the tangent of the dip is double the tangent of such latitude. Mr. Barlow has illustrated this law by experiments on magnetised iron balls acting on small needles at the surfaces; and Biot has deduced the same law from theory.

The following is the inclination for London in the years stated:—

1576	71° 50'
1676	73° 30'
1723	74° 42'
1790	71° 53'
1800	70° 35'
1821	70° 30'
1830	69° 38'
1860	68° 30'

The law of the magnetic forces was a long time undiscovered: Newton supposed it to follow the inverse cube of the distance, or some higher power; for in his experiments, the variation of intensity and the effect of the mutual influences of the magnetic fluids in the bodies themselves being overlooked, an erroneous result was necessarily consequent. However, Mitchell, by a careful revision of the experiments of Dr. Brooke Taylor and of Hauksbee; Coulomb, by his elegant apparatus, the torsion balance; Biot, by the method of observing the times of the oscillations of the small needles acted on; and Hansteen of Christiania, by a series of refined experiments and calculations, have demonstrated the true law of magnetic action,—namely, directly as the intensity, and inversely as the square of the distance. But for the discussion of the whole question, we refer to Harris's 'Rudimentary Magnetism,' part iii. [See also TERRESTRIAL MAGNETISM.]

One essential property by which a magnet differs from soft iron under the magnetic influence, is this: if we separate a magnetic bar into any number of minute parts, each such part will be endowed with polarity, similar to the whole: the position of those poles, or foci of greatest attraction, is permanent in a magnet of a given form; but in

soft iron it will change when the distance of the iron from the influencing magnet is altered.

Halley was sent out, under William and Mary, with the command of two ships, to make magnetic observations in different latitudes, both in the Atlantic and Pacific (in 1698-9), and was the first who constructed a magnetic chart, which possessed at the time great merit for accuracy: the most valued at the present day are those by Hansteen, constructed from observations subsequent to Halley, by various scientific travellers and nautical men, such as Humboldt, Ross, Parry, Scoresby, &c. [TERRESTRIAL MAGNETISM.]

During a thunder-storm the poles of a magnet are frequently inverted, the explanation of which belongs to ELECTRO-MAGNETISM; and the appearance of the aurora borealis is often attended with vibrations of the compass-needle, to the extent of several degrees. The actual mode in which the aurora is produced being still only matter of conjecture, it is impossible to decide whether the aurora is itself the cause of this magnetic phenomenon, or whether both are attributable to some unknown common cause.

The loadstone is frequently combined with substances which have small or no attractive powers; and the poles, or points of contrary nature with respect to attractions and repulsions, being irregularly distributed, counteract in part one another's effects: thus a mass of loadstone often exhibits a comparatively small adhesive force; and it happens at times that, when the mass is broken in pieces, some of the portions, containing a considerable quantity of the attractive material favourably disposed, exercise a greater power than was exhibited by the entire mass. It is found that a piece of loadstone will seldom suspend more than 5 or 10 times its own weight, though some small specimens have been obtained which are said to have suspended more than 200 times their weight.

If a piece of iron be placed in contact with either pole of a magnetised bar, the force of the coherence is that which is due to the direct action of that pole only on the contrary magnetism of the iron: the intensity is at least doubled when the substance to be suspended can be placed at once in contact with both poles; and this is frequently effected by giving to the magnetised bar the form of a horse-shoe, so that the opposite poles may be near one another: but the most effectual method of increasing the power of a magnetic body is that of *arming* it.

Preparatory to arming a piece of loadstone the situation of its axis, that is, of a line joining its poles, must be determined by trial: the loadstone is then reduced to the form of a cube or parallelepiped nearly, having two opposite faces perpendicular to the axis; and these faces are ground very smooth. Two plates of soft iron equal in length and breadth to these sides are applied to the latter so as quite to cover them, and are connected together by a bar of soft iron which is attached to them at the upper end of each (supposing the two plates to be in vertical positions): to this bar is affixed a hook or ring by which the whole apparatus may be suspended.

The inferior extremity of each plate is formed with a foot which projects under the loadstone, so that the latter may rest upon both; and horizontal bands of copper or silver usually surround the loadstone and side pieces in order to keep the whole together. Under the feet is applied a bar or plate of iron, touching both; and this is provided with a ring or hook from which is to be suspended the weight to be held by the attractive force of the loadstone. Artificial magnets have been armed in a similar manner.

The attractive powers situated in the poles of a natural or artificial magnet seem to be diffused over the two surfaces in which those poles are situated; and the plates of iron which cover those surfaces, serving to condense the powers, cause them to act with united energies in the two feet of the apparatus, by which means the power is greatly increased. The feet of the side plates should not however be made to approach each other too nearly; since in such position they would diminish each other's attractive powers.

It is found that a magnet when armed exerts a force more than one hundred times as great as that of the magnet in its natural state; and it has been ascertained that, after as much weight has been applied as the armed magnet will suspend, if at certain intervals of time other weights be added, the magnet will suspend two or three times as much as before.

Daniel Bernoulli discovered by experiment that the attractive forces of magnets vary in proportion to their superficies and not to their masses; a circumstance in accordance with Mr. Barlow's discovery respecting the magnetic attractions of iron spheres.

MAGNETIC ATTRACTION. [MAGNET; MAGNETISM.]

MAGNETIC ELECTRICITY. A term employed to distinguish this force from Frictional Electricity, Voltaic Electricity, Thermo-Electricity, and Animal Electricity.

MAGNETIC INTENSITY. [MAGNET.]

MAGNETISM. If we take a natural or an artificial magnet, and, spreading over a piece of paper a quantity of fine iron filings, place the magnet on the paper, on taking it up, we shall find that the iron filings are attached to it in some degree over all its surface, but they will be principally accumulated at two points situated near the ends of the magnet; these points are called the *poles* of the magnet. Sometimes when a magnetic bar is rolled amongst iron filings, we may find several such points along the bar; the magnet is then said to have *consecutive points*. At present we shall consider only the first or simple case of

two poles, which we may represent by the letters N. and S. When a needle formed of this material is suspended horizontally on a pivot furnished with an agate cap for the purpose of diminishing friction, it assumes a particular direction, nearly north and south. [MAGNET.] The pole N, at the north extremity of the needle thus adjusted, is commonly called the *north pole* of the needle; the other, S, the *south pole*, though the contrary names, as used by Dr. Gilbert, would be more correct in connection with the theory of magnetism.

If we now bring a piece of soft iron near the pole N, it will be attracted to that pole and become attached to it, so that the exertion of a mechanical force is necessary to separate them. In this way a magnet held vertically will sustain a piece of iron, provided the weight of the iron does not exceed the magnetic force. The pole S has a similar attractive power on iron; the cause of this attractive power is called **MAGNETISM**.

We have observed that in a magnetic needle placed horizontally on a pivot, the pole N is turned northwards, and S southwards, nearly: if such a needle be attached to a piece of cork floating on water, it will adjust itself to this direction, the deviation of which from the true north and south line is the *declination* of the needle. If now we invert the position of the needle, so that S is brought into the place previously occupied by N, and *vice versa*, the needle and cork will make a complete revolution, and acquire its original position. Hence we see a distinction between the magnetisms *predominant* at N and at S; the former is called *Austral*, and the latter *Boreal* magnetism. It will be easy to observe the analogy between the mutual relations of the two magnetisms, and those of positive with negative electricities.

We must insulate a conducting electrified substance in order to preserve its electricity, but this is not necessary in the case of a magnet; each fragment of the latter is itself a magnet, possessing its north and south poles, and the same view may be extended to its constituent particles. A non-conducting energy, called the *coercive power*, exists therefore in magnetic substances, by which the loss of magnetism when developed is prevented, and by which also the poles N and S are situated in a determinate position relative to the body of the magnet. This is not the case with soft iron, which has not the coercive force.

The effect of the magnetic forces is considerably modified when substances which are capable of readily becoming magnetic by influence are situated near the magnet; and a similar effect takes place by the decomposition of the neutral electricities when under the influence of an electrified body. [ELECTRICITY.] The transmission of the magnetic force through interposed bodies may be observed familiarly by placing a common sewing-needle on a smooth horizontal board, and moving a strong magnet underneath the board: the needle will roll or revolve along the board according to the peculiar motions given to the magnet.

Let us next consider the action of magnets on each other. For this purpose make two magnets or magnetic needles to float on water, distinguishing the poles of one as before by N and S, and of the other by N' and S'. Bring either the pole N near to N', or S to S': the needles or magnets will separate to a greater distance, and with the greater energy the nearer these poles are placed to each other. On the contrary, if we bring N and S' near each other, the needles will approach and unite those points, and the same happens when the points N' and S are made contiguous: hence this law—*magnetisms of the same name are mutually repulsive; those of contrary names are mutually attractive*. In the article **ELECTRICITY**, we have shown that the same law is true with respect to the two electricities.

The mass of the globe contains various sources of magnetism [MAGNET]; and since a magnetic needle freely suspended acquires a determinate position, it follows from this law that the magnetism at the south extremity S is Boreal, that is, of the same name as the terrestrial magnetism which is predominant in the northern hemisphere, being repelled therefrom; and the magnetism at the north extremity N is for a like reason Austral. The law of magnetic force at different distances is expressed by the inverse square of the distance: one mode of verifying this law is by observing the times of the oscillations of a small fine wire, suspended in a plane perpendicular to the magnetic meridian (in order to neutralise the magnetising influence of the earth), and subjected to the action of a powerful magnet.

We can, by combining these laws, explain the manner in which soft iron, cobalt, and nickel are attracted or suspended by a magnet. These metals, when chemically pure, contain both the austral and boreal magnetism in a combined state, in consequence of their want of coercive power. When a piece of soft iron is brought near the pole N, which contains the austral fluid, the austral magnetism of the iron is repelled to the farther extremity, and the boreal attracted to the nearer extremity of the iron relative to the point N: this disposition of the fluid takes place immediately, and the law of force above announced relative to the distances causes the attraction of the fluid at N, on the boreal fluid of the soft iron, to exceed its repulsion on the austral, which is more remote from N: the total effect, in virtue of this excess, is therefore necessarily attractive. When the iron however is removed from this influence, its natural magnetisms again recombine. This will not be the case if, instead of soft iron, we use hardened iron or steel: the decomposition of the natural magnetisms takes place with greater difficulty, in consequence of the coercive power which protects their actual disposition; but if we use a powerful magnet at one extremity of a steel needle, or, which is more effectual, a pair of strong magnets

at both extremities, the north pole of one and the south pole of the other being brought in contact with the needle, the decomposition will be partially effected, and will likewise be retained by the same coercive power which opposed its development; and agreeably with the magnetic laws of repulsion and attraction, that point of the needle in contact with the south pole will become a north pole of the needle, and the other a south pole. This method of producing magnetism is liable to the objections both of producing feeble magnetism and also producing consecutive points.

The quantities of the austral and boreal magnetic fluids in all magnetic bodies are equal; for when we bestow magnetic qualities on iron or steel by the influence of loadstones, hammering, sudden cooling in the magnetic meridian, &c., no new magnetism is communicated; but the natural magnetisms, which previously neutralised each other, are now decomposed. Again, if a magnetic needle be freely suspended by its centre of gravity, the action of terrestrial magnetism produces no linear motion, but only imposes a direction on the magnetic axis: now all the boreal fluid in the globe attracts all the austral fluid of the needle, and *vice versa*, while the like fluids in both repel; hence a motion of progression would be generated, unless the resultant of the repulsive forces on the needle was exactly equal and of an opposite direction to the resultant of all the attractive forces; and the rotatory motion of the needle shows that the points of application of these forces are different; but the intensity of terrestrial magnetism may be regarded as uniform throughout the extent of the needle, and its direction parallel. In order therefore that the resultants should be equal and contrary, the sums of the boreal and austral forces of the needle must be equal. In this respect magnetism resembles the natural electricities of all substances.

The development of magnetism in bodies, whether by terrestrial action or the influence of loadstones, is analogous to the decomposition of the natural electricities in a system of conducting bodies separated by non-conductors under the influence of an external body and their own natural action: hence when magnetism is communicated by a loadstone, even when in contact, the latter loses none of its own magnetism, as it acts solely by influence; whereas in conducting electrified bodies, contact will communicate electricity: the coercive force of magnets therefore extends even to their surfaces. In fact the reaction of the substance magnetised by influence tends to a further decomposition of the fluids of the magnetising body, and this gives it greater energy, unless when it is magnetised to saturation, that is, when the internal magnetic forces are equal to the coercive power; for then any further development of the fluids would be only temporary, and a reunion would take place immediately.

The dipping-needle is a magnetic needle, the opposite poles of which possess equal magnetic intensities. It is attached to the centre of a vertical circle, and its motion is confined to the plane of this circle. The circle has a motion in azimuth about a vertical axis, and within a fixed horizontal circle, both circles being graduated. When the vertical circle is turned round its axis until the needle acquires a vertical position, the plane of the circle is then perpendicular to that of the magnetic meridian, and hence by means of the horizontal circle the position of this meridian plane becomes known. The vertical circle with the needle is now brought to coincide with the meridian plane, and the angular depression of the north pole of the horizon, or more strictly of the magnetic axis, may be read off the graduated limb of the vertical circle, and measures the dip. The right line joining the north and south poles of the needle is nearly coincident with the magnetic axis, but the latter may be ascertained more accurately by inverting the needle and taking the mean direction between its two positions of equilibrium. There are other methods of adjusting the dipping-needle, but in every method it requires great delicacy and minute attention to all parts of the adjustment.

If we place a bar of soft iron, suspended by a collection of silk strings at its middle, in a direction parallel to the magnetic axis of the dipping-needle, the action of terrestrial magnetism will have full effect on the bar, its natural magnetisms will be decomposed, and it will acquire a polarity similar to that of the needle, its poles repelling the similar poles of the needle, and attracting the contrary poles. Its want of coercive power prevents it from retaining the polarity of its different parts when the bar is moved into other positions; for if we invert the position of the bar, that point which was primitively the north pole will now become the south, and *vice versa*, under the effects of a new decomposition of its magnetisms by terrestrial influence. If however the bar be left for a long time in the direction of the magnetic axis, or if it be heated to a red heat and suddenly cooled by immersion in water, it will acquire a coercive force, and become permanently magnetic. Iron crosses, weathercocks, &c., which have been long kept in a fixed position, or have been struck by lightning, acquire magnetic properties in the manner above described.

It is a remarkable circumstance connected with the change of molecular disposition caused by the action of heat, that if we gradually heat a bar of iron, the intensity of its action on a magnet increases, and arrives at a maximum when the bar is brought to a cherry-red heat: with higher degrees of heat the intensity is diminished, and is totally inappreciable when the bar has reached a bright white heat; on cooling it recovers its powers of action by similar steps, and the same law holds true if the magnet be heated instead of the bar. Hence in producing

the greatest development of magnetism by influence, we see the advantage of using iron or steel bars at a red heat. [LIGHTNING.]

Magnetism may be developed in iron, steel, cobalt, and nickel, by other means than the influence of bodies already magnetised, as twisting, hammering, electrical discharges, and galvanic currents. [ELECTRO-MAGNETISM.] If we place a bar of iron in a vertical position, and give it a series of slight blows with a hammer or poker, it will acquire a feeble degree of magnetism; hence it happens that the anvils and other tools employed in smithies are endowed with magnetism. In all such cases the mechanical operations tend to bestow a coercive power, while the terrestrial magnetism separates the fluids in the body.

Cavallo, Benett, and Coulomb remarked the indications of magnetism given by various substances, as copper, silver, &c. It is particularly observable in hammered copper, and scarcely perceptible when the copper has been cast. Coulomb formed very fine needles of various substances, and suspending them by silk strings between the opposite poles of two powerful loadstones, found that they were acted on by the latter. This phenomenon was attributed to the existence of minute quantities of iron, or iron compounds in those different bodies, and the intensity of the magnetic action Coulomb found from direct experiments to be proportional to the quantities of iron contained in the bodies, and he afterwards applied this principle to discover the quantity of iron contained in impure metals. Faraday has however shown in the discovery of *diamagnetism*, that a much deeper truth was involved in the subject, as will be noticed more fully presently.

From the preceding observations on the properties of the magnetic fluids it will be easy to understand the principles upon which the various modes of constructing artificial magnets are founded, which we shall now briefly notice. The earliest method of magnetising a bar of hard iron or steel was by drawing it throughout its whole extent at right angles over one of the poles of a strong magnet. In this case if we suppose that pole which contains the austral fluid to be used, the first contact with the bar decomposes its neutral magnetisms, attracting to the point of contact the boreal and repelling the austral; the successive parts of the bar are subject to a similar decomposition of their fluids, but it is evident that the effect of each previous decomposition neutralises the succeeding, except at the extremities; the magnetism thus developed is therefore feeble, and apparent only at the extremities of the bars, or in some consecutive points formed by peculiarities in the material of the bar, or in the mode of operation. Dr. G. Knight greatly improved the mode of magnetising bars in the following manner: he joined two strongly magnetised bars by their ends bearing contrary names, and placing on them in the direction of their length a small steel bar heated to a cherry-red heat, with its middle on the point of junction of the magnetic bars, he made each of them to rub on the corresponding extremity of this steel bar, and the latter when removed was found to be strongly magnetised. In this method not only does the presence of the second magnet favour the decomposition of the magnetic fluids, but the intensity of the action of the magnetic forces is greatly increased by the elevated temperature of the steel bar.

Du Hamel placed two steel bars of equal length parallel to each other, connecting their corresponding extremities by pieces of soft iron interposed; then taking two bundles of magnetic bars, he united their poles of contrary name near the middle of one of the steel bars, and by inclining the bundles made one of them pass towards one extremity of the other bar, the second passing in the contrary direction, and then successively repeated the operation, when both the steel bars became strongly magnetised, but with contrary magnetisms at the corresponding extremities of each. In this method the decomposition of the neutral magnetisms of the interposed pieces of soft iron adds to the effect produced by the contact of the magnetised bundles with the steel bars.

Epinus, adopting a similar method, preferred interposing strong magnets instead of soft iron, the relative position of the poles of the two magnets being reversed; Coulomb combined the advantages of these different methods by composing his magnetised bundles of bars at a cherry-red heat. A fine steel needle may be very strongly magnetised by being placed in the axis of a wire twisted into the form of a helix, the extremities of which are brought in contact with the wires of a powerful galvanic battery. The poles of a bar magnetised to saturation are near its extremities, within generally a few lines, while the intensity becomes insensible at the distance of a few inches; in a thin bar the intensity may be represented by the difference of the ordinates of two logarithmic curves, the origin of one being at the austral, and of the others at the boreal extremity of the needle.

When bodies containing neutral magnetisms are made to rotate rapidly round an axis, the magnetism becomes developed and acts on the needle; thus a plate of copper made to revolve rapidly in a horizontal plane will influence a compass-needle placed over it, and produce in it a rotation in the same direction, on which subject several valuable observations have been made by M. Arago, Sir John Herschel, and others. It has also produced a second mathematical memoir from M. Poisson, in which the mechanical force generated by rotation is introduced into the general equations deduced from his theory of the distribution of magnetism in bodies. The phenomena are however now absorbed into MAGNETO-ELECTRICITY.

The consideration of the distribution of magnetism throughout the

globe has led to various explanatory hypotheses since the time of Halley; the position, the number, and the motions of the points which may be regarded as poles of terrestrial magnetism, have been all subjects of discussion and of opinions formed on inconclusive grounds. But the consideration of this subject as well as an account of the dip, variation, and intensity, at different parts of the earth, as well as the consideration of the magnetic equator and poles, and the magnetic observatories that have been erected in different places will be best considered under TERRESTRIAL MAGNETISM.

Some important discoveries in magnetism have been made of late years, and some knowledge has been gained as to the molecular changes produced by the magnetic condition. Mr. Joule has shown that a bar of iron in being magnetised increases in length, while its breadth diminishes. The greatest elongation observed by him amounted to the 180-thousandth of the length of the bar. He also states, that the elongation is proportional to the square of the developed magnetic intensity. He has also found that iron wires of a certain tension diminish in length instead of increasing, and that at a certain tension, there is no alteration in length. The sounds produced in making an electro-magnet are noticed under ELECTRO-MAGNETISM. *Circular magnetic polarisation* is a new and interesting branch of physical science, which we owe to the genius of Faraday. A few words on the subject will suffice here:—if in the course of a ray of light polarised by reflection, a bar of heavy glass (silico-borate of lead) be placed, it will be seen by a Nicol's prism that the ray is still polarised, and in the same plane as before. If, however, the poles of a powerful electro-magnet be brought near the bar of glass, in such a position that the direction of the ray through the glass is parallel to the straight line which joins the poles, a remarkable effect will be produced on making the electro-magnet. Supposing the Nicol's prism to be in the position of complete extinction, so that no light is transmitted through it, and the voltaic current be then sent through the coils of an electro-magnet, the light will immediately reappear through the prism, and will continue as long as the electro-magnetic force be maintained, and no longer. [POLARISATION]. In the course of these researches, Faraday noticed that when the bar of heavy glass was suspended between the poles of the electro-magnet, no sooner was the magnet made, by connecting the coils with the battery, than the bar of glass ceased to swing indifferently, but moved round and took up a position at right angles to the direction that would be taken by a bar of soft iron placed in the same part of the magnetic field. The bar made a few vibrations round this position, and finally settled in it; and when displaced, it returned to it, and settled as before in this position, which Faraday calls the *equatorial*, to distinguish it from the position assumed by an iron bar under the same circumstances, and which he terms the *axial*.

On examining other bodies, it was found that every known substance when brought under the influence of a powerful electro-magnetic force, assumed either an axial or an equatorial position with respect to the poles. Faraday was led to regard all substances in nature as magnetic: those bodies which took up an axial position, or were attracted by the poles, he termed *para-magnetic*, while those bodies which were repelled, and consequently took up an equatorial position, he termed *dia-magnetic*. A piece of hæmatitic iron ore which is not acted on by an ordinary magnet will point axially when suspended between the poles of an electro-magnet; and a sheet of writing-paper rolled up into a short cylinder will also point axially in consequence of the minute portion of iron or of cobalt which it contains. The salts of the magnetic metals, when the latter form the base, were also found to be magnetic, such for example as crystals of proto-sulphate of iron, and solutions of such salts in water contained in a thin glass tube (the glass not being magnetic) assumed an axial position. Solutions of sulphate of nickel and sulphate of cobalt behaved in a similar manner and the salts of chromium and manganese were also found to be magnetic, whence it was inferred that the metals themselves are so. A stick of phosphorus assumes the equatorial position, as do also bismuth and antimony; and organic substances, such as slices of wood, apple, potato, flesh, &c. These are *dia-magnetic*, but not strongly so. Sulphur and india-rubber are decidedly repelled. Among liquids, alcohol and ether are *dia-magnetic*, and water still more so. Even the different gases and vapours were found to be acted on by the magnet, and among other modes of showing the action, soap-bubbles were blown with each gas in succession upon the end of a capillary tube, and being suspended near the pole of the magnet the circuit was completed, when the bubble was attracted or repelled according as the gas was magnetic or *dia-magnetic*. Oxygen was found to be powerfully magnetic: all other gases were found to be *dia-magnetic*, with the exception perhaps of nitrous oxide. Elevation of temperature was found to increase the *dia-magnetic* condition, a stream of hot oxygen being *dia-magnetic* in an atmosphere of cold oxygen. Faraday has suggested that this diminution of oxygen in magnetic intensity, as the temperature rises, may account in some way for the diurnal variations of the needle. A diminished pressure was found to lower the *dia-magnetic* force; the magnetic power of oxygen being diminished by a diminution of density. Nitrogen, which is a *dia-magnetic*, does not seem to undergo any change in its magnetic relations, by variations in density and temperature. In experiments of this nature the gases were enclosed in thin glass tubes in connection with a delicate torsion balance. The flame of burning bodies, as of a taper for example, when

placed between the poles of the magnet is repelled towards either side, and even divides into two streams which pass off horizontally, one on either side, in the equatorial direction.

It is important to observe, that the nature of the medium in which a substance is placed, has an influence on the magnetic condition of matter; thus a rod of glass suspended horizontally in water, which is dia-magnetic, will point axially, but if the same rod be suspended in a solution of sulphate of iron, which is magnetic, it will point equatorially. So also, a tube filled with a solution of sulphate of iron, will appear to be magnetic if placed in pure water, but if placed in a stronger solution of sulphate of iron, it will be dia-magnetic. The same body may also be magnetic or dia-magnetic, according as it forms the base or electro-positive constituent of a compound, or the acid or electro-negative constituent. Iron for example, in the crystals of green vitriol acts as a base, and makes the crystals magnetic, but in the yellow prussiate of potash, where the iron is not a base but an electro-negative-constituent, the crystals are dia-magnetic; so also bichromate of potash is dia-magnetic, the chromium acting the part of an acid, while sulphate of chromium is magnetic, for here chromium acts as a base. Tyndall and Knoblauch ('Phil. Mag.' 1850), have shown that the arrangement of the component particles of a body will determine whether it be magnetic or dia-magnetic. For example, carbonate of iron is magnetic; if reduced to fine powder and formed into a cylinder by means of gum-water, it will point axially, but if compressed into a plate, this plate will set with its faces parallel to the equatorial direction. In fact, the parts brought nearest together by compression, were those which exhibited the dia-magnetic, or the magnetic action most strongly. In this way the phenomena, discovered by Plücker, were accounted for that in doubly refracting crystals the optic axis assumes a definite direction under the influence of the electro-magnet; for it is along this axis that the greatest condensation of the particles has probably taken place. There are many other remarkable circumstances connected with dia-magnetism, for which we must refer to Faraday's original memoirs, which have been published in a collected form, and also to Tyndall's papers, especially those in the 'Philosophical Transactions' for 1855, 1856, in which it is shown among other results, that the dia-magnetic repulsion, as measured by the torsion balance, is as the square of the intensity of the current.

MAGNETISM, ANIMAL. [MESMERISM.]

MAGNETO-ELECTRICITY. If a wire which joins the two ends of a voltaic battery [GALVANISM] and consequently through which a voltaic-current is passing, be arranged in such a manner as to be parallel with a second wire, the two ends of which are connected with a sensitive galvanometer, no action on the second wire will be perceived so long as the current is allowed to pass uninterruptedly through the first; but if the current through the first wire, called the *primary* current, be suddenly arrested by breaking off its connection with the battery, a current of momentary duration will be produced in the second wire; this which is called the *secondary* current is said to be direct, or in the same direction as that of the battery wire. On again connecting the first wire with the battery a momentary current or electric wave is again sent through the second wire; but it is now inverse or in a direction opposite to that of the primary current.

The term *volta-electric-induction* was applied by Faraday to these phenomena. Their effects may be augmented by employing coils in such a way that that which conveys the primary current, known as the *primary coil*, shall be placed in the axis of the coil in which the secondary current is generated, the ends of this the *secondary coil* being connected with the ends of the galvanometer. The moment the primary coil is connected with the battery the needle will receive a powerful impulse; but will regain its original position after a few oscillations, although the current through the primary coil is kept up; but no sooner is the primary coil disconnected from the battery than the needle will be powerfully impelled in an opposite direction. Similar phenomena may be produced if the primary coil, while connected with the battery, be made suddenly to approach to, or be removed from the secondary coil, in connection with the galvanometer. In approaching the coil the secondary current is inverse; but in withdrawing it, it is direct. If instead of the galvanometer, a small helix be connected with the secondary coil, a steel wire may be magnetised by the induction of these instantaneous secondary currents. If a Leyden jar be discharged through an insulated primary coil a secondary current will be generated in the other helix. Since then voltaic and frictional electricity may be made to produce magnetism, it was natural to suppose that magnetism could be made to produce electricity. We owe to Faraday the method of producing this result. An experiment will illustrate the conditions required to produce it. The ends of a copper helix are connected with a galvanometer by wires several feet in length in order that the instrument may not be directly acted on by the magnet which is to be employed. Now if a permanent magnet be introduced into the axis of the helix, a current in the wire is instantly produced, as marked by the deflexion of the galvanometer needle; if the magnet be kept at rest within the helix, the needle after a few oscillations returns to zero; but the act of withdrawing the magnet is sufficient to deflect the galvanometer needle in the opposite direction and to the same extent as before. the direction of the current depends on which pole of the magnet is introduced into the helix, and also upon whether the helix be left-

handed or right-handed. On placing a bar of soft iron in the helix no current is produced; but if the opposite poles of two bar-magnets be brought in contact with the ends of the soft iron, a momentary current is produced.

The secondary currents thus obtained by magnetic induction have considerable intensity, and if when the current is passing the circuit be broken a bright spark will be seen at the point of interruption. Ruhmkorff's coil is an improved form of apparatus for exhibiting these secondary currents. The primary or inner coil A A' is a stouter and shorter wire than the secondary coil, B B; this is a very long thin wire insulated by silk, each layer of coils being carefully insulated from the adjacent ones. In a ten-inch coil the primary wire is 132 feet long, and the secondary wire 26,246 feet long. A bundle of soft iron wire, M, is placed in the axis of the coils, while at + and - are binding screws for connecting the primary coil with a voltaic battery. The primary coil is broken at c and d, d being a small armature of soft

iron, faced below with platinum, the upper surface of c being also faced with platinum. When c and d are in contact the current circulates through A A; but in doing so the iron core M becomes magnetic, attracts d, the effect of which is to interrupt the current through A A, and the magnetism in M disappears; whereupon the hammer d falls upon c, the current through A A is again made to flow, d is again attracted, the current is again interrupted, and in this way the voltaic battery serves as a means for making and breaking the contact, and so rapid is the action that the hammer rises and falls several hundred times in a minute, and a powerful current is induced in the secondary coil B B by each of these momentary currents in A A, the effect of which is a continuous stream of sparks between the insulated ends of the secondary wire e f, and shocks of the most painful and dangerous character are produced. The power of the instrument may be greatly increased by connecting the primary wire with an arrangement called the *condenser*, consisting of oiled silk covered with tin-foil, folded between two other surfaces of silk and packed in a flat wooden case; the two coatings are connected with binding screws attached to c and d in the primary current. The effect of this condenser is to increase the intensity of the secondary current, so that with a large coil and careful attention to the insulation of the conducting wires, powerful sparks ten or eleven inches in length have been obtained. By means of this coil, electricity of low tension may be made to equal in intensity that of an ordinary plate machine, while the quantity is greatly increased. If the secondary coil be allowed to discharge in an exhausted receiver the phenomenon of the auroral light may be obtained in a very beautiful manner, through an interval of several feet. By arranging the discharge in various ways, as explained by Mr. Gassiot (Phil. Trans., 1858, 1859) in long tubes partially exhausted or containing gases of different kinds, the luminous portion is traversed by a series of dark bands, which are rendered much more distinct by the presence of a small portion of phosphorus vapour. [ELECTRICAL Egg.] The magnet has a powerful action on these stratified bands and luminous discharges.

When the terminal plates of a voltaic battery are connected by means of a long wire coiled into a helix, a brilliant spark is produced on breaking contact, arising from a current passing through the wire in the same direction as that from the battery. The inductive action of the battery on the wire may be diverted by placing a second helix within the primary coil or exterior to it. By placing an iron core within the helical conducting wire the current becomes sufficiently intense on breaking contact to give a powerful shock, although the battery be of very small power. Professor Henry has shown ('Philosophical Magazine,' 1840) that a succession of induced currents may be formed by the action of coils upon each other. If, for example, the coil in connection with the battery be in the form of a flat spiral, and we call this A, and two other flat coils running into each other, namely, B and C, be arranged so that B shall rest on A and C on the table, there will be a momentary current in B and C every time the connection of the coil A with the battery is broken. If two other coils D and E, be arranged so that D shall rest on C and E on the table, the induced current in C will produce a current of the third order in D E. If a flat coil F be placed over E with its ends united by a small helix G, a current of the fourth order will be obtained. In this arrangement the secondary current B C will be direct; the current of the third order D E inverse; the current of the fourth order F G direct. The coils must be carefully insulated, and with care currents even up to the seventh order may be obtained, the currents being alternately direct and inverse. Similar currents are generated whenever the primary circuit is completed, but in such case the direction of the current is reversed. These induced currents give shocks, magnetise steel, and effect chemical decompositions.

Many years ago the motions of a magnet under the influence of a rotating copper-plate, known as "Arago's Rotations," excited considerable speculation and inquiry [MAGNETISM], until Faraday gave the true explanation. The leading experiment may be shown by suspending a bar magnet freely by its centre, so that it can move in a horizontal plane, while beneath it a circular disc of copper being made to rotate, the magnet will move round in the same direction as the disc, even though a sheet of paper or of glass be interposed between them. Discs of other metals on being rotated give motion to the magnet, but none so readily as copper. A narrow strip cut out of the disc, from the circumference to the centre, is sufficient to prevent the disc having any action on the magnet when the former is made to rotate. If the cut edges of the disc be connected by a piece of wire, the power of the disc over the magnet is completely restored.

In investigating these phenomena, Faraday found that when a conducting body is passed before the pole of a magnet, or between its opposite poles, so as to cut the magnetic curves at right angles, electrical currents are produced across the metal, transverse to the direction of motion. If, for example, the copper disc *c*, be made to revolve in the direction of the arrows at the edge, between the poles *N S* of a horse-

shoe magnet, and a wire *w*, connected with one end of the galvanometer *g*, be pressed against the centre of the disc, while the other wire *w'*, proceeding from the galvanometer, rests against the edge of the disc, between the magnetic poles, a current will flow from the centre to the circumference of the disc, and then through the wires in the direction of the arrows. If the disc revolve in the opposite direction the current will flow from the edge to the centre of the disc. Now in Arago's experiment, when the copper disc revolves beneath the magnet, it cuts the magnetic curves at right angles (adopting Ampère's view that a series of electric currents are perpetually circulating around the component particles of a bar magnet, in planes at right angles to the magnetic axis), in which case currents are produced beneath the north pole from the centre of the plate towards the circumference. These currents proceed from the circumference to the centre, beneath the south pole, traversing the diameter of the plate, parallel to the magnet, and return by the more distant parts of the plate. Such currents exert a repulsive action on the magnet in a direction coinciding with the motion, and there are no currents until the magnet or the plate be in motion.

More convenient arrangements than the above have been contrived for the generation of magneto-electric currents, the best known of which is Saxton's *magneto-electric machine*. It consists of a powerful horse-shoe magnet placed horizontally upon one of its sides, and opposite and nearly in contact with its poles an armature of soft iron *a b* is made to revolve upon a horizontal axis *A*. In the figure the horse-shoe magnet is not shown. The armature consists of two pieces of iron, about 2 inches long, attached to a cross-piece of iron *x*, at such a distance as to be opposite the middle of each pole of the horse-shoe magnet. Each piece of iron, *a b*, contains a coil, *c d*, of fine copper-wire covered with silk to insulate the coils. The corresponding ends of each of these coils are connected together; one pair, *e f*, is attached to the spindle *s*, on which the armature revolves, and through it is connected with a circular copper disc, *i*, the edge of which dips into a cup

of mercury, *m*, while the other pair of wires, *g h*, is connected with a stout piece of copper that passes through the axis of the spindle *s*, from which it is electrically insulated, and terminates in a slip of copper, *k*, which is placed nearly at right angles to the cross-piece *x*. Beneath *k* is a second cup of mercury, *l*, which can be made to communicate with the cup *m* by a wire or some other conductor. During the revolution of the armature, the points of the slip *k* alternately dip into the mercury and rise above it. Now when *l* and *m* are con-

nected, and the point *k* beneath the mercury, the circuit is complete. The ends of the armature, *a b*, are exactly opposite the ends of the horse-shoe magnet, but by giving motion to the axis they quit that position, lose their magnetism, the current is broken, the slip *k* leaves the mercury, and in doing so produces a bright spark. If the connection between the mercury cups be made by means of wires, terminating in copper cylinders, held one in each hand, a rapid succession of powerful shocks will be felt on causing the armature to rotate. Water and saline solutions may be decomposed by transmitting these currents through them. For currents of high intensity, such as are required for these decompositions, the armature should be furnished with a great length of thin wire; but for the display of large sparks, and the ignition of platinum wire, &c., a shorter length of thicker wire may be used. It should be observed that the currents produced during each half revolution in the two limbs of the armature are in opposite directions, but in some machines arrangements are made by means of *commutators* [TELEGRAPH, ELECTRIC] for keeping up a continuous current in a uniform direction. This is of importance, since magneto-electric machines now often take the place of the voltaic battery in the electric telegraph, and in the process of electro-silvering, and electro-gilding [ELECTRO-METALLURGY]; and a powerful machine of this kind has been employed by Mr. Holmes for producing a light of great steadiness and intensity between two points of gas coke. This light has been experimentally and successfully tried at the South Foreland Light-house.

MAGNETOMETER. A name applied to those instruments, the function of which is to measure any of the magnetic elements. These instruments will be best described in connection with their subject, namely, TERRESTRIAL MAGNETISM.

MAGNIFYING POWER. [MICROSCOPE; TELESCOPE.]

MAGNITUDE. This term is generally used synonymously with quantity, and is sometimes even confounded with number. The distinction between the first two terms is not more marked than this: he who answers the question "how much?" describes the quantity, and he who answers "how great?" describes the magnitude. But since magnitude is generally used in our language as applied to amount of space, we may best describe our own idiom by laying down quantity as the general term, and stating magnitude to mean usually the quantity of space. The term however must be considered, in a mathematical point of view, as originating with Euclid (whose word is μέγεθος), and it is used by him, not particularly as applied to space, but also to everything which admits of the introduction of the notion of greater or less. In this sense, then, we have many magnitudes (all moral qualities, for instance) which are not the object of mathematical reasoning. So necessary is the notion of magnitude to our conception even of things which we cannot measure, that we borrow idioms from subjects within the province of mathematics. Thus we speak of force of mind, and of it being greater in one individual than in another. According to the definition of magnitude,—namely, "that of which greater or less can be predicated, when two of the same kind are compared together," it follows that we include both mental as well as material objects of conception. But the mathematics interpose the postulate that no such object can be made matter of exact reasoning, unless in cases which admit of the comparison being performed according to some method the results of which shall be self-evident, and inseparable from our notion of the thing measured. Let *A* and *B* be two magnitudes of the same kind; they are then, and then only, the objects of mathematical comparison, when other magnitudes equal to *A* and *B* can be found, and added together as often as may be desired; and when, moreover, any collection of *A*'s can be compared with a collection of *B*'s, so as to ascertain which is greater or less than the other. Angles furnish an instance of magnitude the conception of which is exceedingly vague in the mind of most beginners, but which takes precision and certainty in the course of mathematical study. Magnitudes, thus capable of comparison, are the objects of the doctrine of PROPORTION. [See also NUMBER; QUANTITY.] That part of geometry which precedes proportion considers only the simple alternative of equal or unequal, modes of inequality being necessarily deferred until after that consideration.

By the magnitude of any bounded space the mathematician means the results of measurement which will be described in SOLID, &c., DIMENSIONS; but the common idiom refers to that which the mathematician calls, for distinction, *apparent* magnitude. It is correct, in the common meaning of the term, to say, that a man at a little distance from the eye is larger than a remote mountain. In thus judging of objects, the angles which they subtend at the eye furnish the means of comparison. Experience, derived from the combination of sight and touch, teaches us how to make those deductions which are necessary before we can learn the absolute from the apparent magnitude.

It is soon found that an object, as it recedes, grows smaller; that is, subtends a less angle. It is also seen that the recess is accompanied by a loss of brightness and distinctness. The former is a consequence of the loss of light which takes place in its passage through the air; were it not for this, the same object would be equally bright at all distances; for though the quantity of light which enters the eye is diminished by increase of distance, yet the surface from which the light appears to proceed is diminished in the same proportion. The loss of distinctness is a consequence, first of the loss of light, next of

the different proportion in which different colours are lost : the effect of the interposed atmosphere amounting to laying on more or less of the blue colour of the atmosphere over the whole. Our perception of magnitude depends both on the subtended angle and on the distinctness : we learn from experience, that of two objects seen under the same angle, the less distinct, as being the more distant, must be the larger. That habit is our guide can readily be shown by producing instances in which we are deceived, the object being either such as is not commonly seen, or seen under unusual circumstances. A colossal statue mounted on a column does not suggest the idea of a man of unusual size to persons in general, unless when some person mounts the same height and affords means of comparison. In a fog, which diminishes the distinctness of objects, but does not affect the angles under which they are seen, these objects are sensibly increased in apparent size ; and distant hills appear nearer in a clear day than in a hazy one. Those who wear spectacles may satisfy themselves by breathing on the glasses, and watching an object as the moisture evaporates, that increase of distinctness gives apparent approximation.

The angle subtended by an object is inversely as its distance, which is sufficiently near for common purposes, when angles are small, which is generally the case ; and a man of 6 feet high, at the distance of 100 feet, is seen under an angle of $3^{\circ} 26'$. The sun is seen under an angle of $32'$, and the moon under an angle of $29\frac{1}{2}'$ to $33\frac{1}{2}'$.

MAHĀBHĀRATA, or BHĀRATA ("belonging to Bhārata and his descendants"), the most celebrated epic poem of the Hindus after the Rāmāyana. A passage in the introductory part of the work (1, 2296) has given ground for the assertion that it contains the round number of a hundred thousand distichs or slocās ; but in order to complete this enormous amount, the 'Harivansa,' a mythological history of Krishna, and sundry other pieces, have been added. The eighteen component fictions (Parva) of the 'Mahābhārata' contain about 85,000 slocās, and even these may be reduced to 24,000 distichs, of which the original 'Bhārata,' without its episodes, is said to have formerly consisted. (1, 101.) The principal subject of the 'Mahābhārata,' to which its middle sections particularly are consecrated, is a long civil war between two dynasties of ancient India, the Kurus and Pāndus. Both were descended from Bhārata, king of Hastinapur, whose first-born son, Dhritarāshtra the father of Duryodhana and the Kurus, ought to have succeeded to the throne ; but this prince being blind, the sceptre was seized by his cousin Yudhishtira, the eldest of the five Pāndu princes. At first the usurper was driven off by his uncle Duryodhana, and even banished to a wilderness for twelve years ; but as the Pāndu brethren were favoured by their friend and ally, the heavenly Krishna, and as they were themselves, according to the legend, begotten by several deities, after a long struggle against the Kuru princes, and after many perilous adventures and bloody exploits, they were finally established in the sovereignty of India.

In this main texture of the 'Mahābhārata' is interwoven a great variety of episodes ; or more properly speaking, the history of the Pāndus and Kurus is the leading thread by which an immense collection of ancient traditions, moral reflections, poetical descriptions, and popular stories of every kind, has been connected. It is very important to observe that these accessory elements, which now form almost three-fourths of the whole epopee, are stated in the poem itself not to be constituent parts of the original 'Bhārata ;' in fact they are for the most part very loosely inserted ; and as many of them are epic productions of considerable length, the principal theme is not only frequently interrupted by intervening episodes, but often totally lost sight of, even when the most active progression should be expected. Thus, for instance, the metaphysical system of Patanjali is propounded by Krishna, in the eighteen lectures of the much admired Bhagavadgītā, just when the army stands disposed in full array and ready for battle. Besides a vast number of various short tales and fictions of every description occasionally inserted, the episodical compositions of the 'Mahābhārata' may be divided into two general classes of a more distinct character and of peculiar importance. The first class, to which the early sections of the 'Mahābhārata' are particularly consecrated, is occupied in solving theogonical and cosmogonical problems, blended with those wild and fantastical conceptions by which the metaphysical mind of the Hindus is so deeply attracted. To these, in the last chapters of the work, and after the conclusion of the great war, are added didactic and moral episodes on religious duties and sacrifices, on solitary and penitential life, and on final beatitude, forming almost a complete system of Indian ethics, and a compendium of the Brahminical faith. The second class of episodes, which may, although in some respect improperly, be called historical, consists of various and ample traditions of former epochs, and is occupied in recording the origin, genealogy, and history of ancient kings and heroes ; in giving an account of their government and practice of warfare, their individual adventures, and their splendid actions ; and in exhibiting their piety and devotion in fulfilling those duties of a religious life by which the favours of the heavenly beings are to be acquired. These and similar narratives are chiefly accumulated in the third and longest section of the 'Mahābhārata,' called Vanaparvan (book of the forest), where they are told by the Brahminical sage Markhandeya, for the purpose of entertaining, consoling, and animating the dejected spirit of the Pāndu princes during their exile in the wilderness. In this respect the episodical pieces of the 'Mahābhārata' may be compared with the

rhapsodies sung by Phemius and Demodocus in the Homeric poems, and as many of them are marked with a peculiar simplicity of manners and customs, they might almost seem of an older date than the main body of the epopee, of which they are totally independent. This leads us to the original composition of the 'Mahābhārata,' which in the introductory part of the poem is thus related.

The most celebrated sages, with their disciples, being assembled at a splendid sacrificial festival, the venerable Krishna Dvaipāyana, with the surname of Vyāsa, who had been an eye-witness of the great civil war, is requested by king Janamejaya to give an account of those bloody events, in which, two generations ago, his own ancestors had played a fatal part. This task, being declined by Vyāsa himself, is readily performed by one of his disciples, Vaisampāyana, who being duly instructed, and from memory familiar with the heroic poem, recites it at full length to the listening assembly. A similar festival being afterwards celebrated by king Saunaka, the same proceedings are repeated, and Sauti, whose father had been a disciple of Vyāsa, undertakes the recital of what is now considered the original 'Bhārata.' Neither in these nor in other instances is a written copy of the text mentioned ; it was in fact only committed to memory and handed down by oral tradition, until the increasing mass of subsequent episodes, more or less connected with the primitive subject, urged the necessity of a final arrangement ; and, to avoid further interpolations, a summary of the contents was prefixed to the whole collection, now existing under the name of 'Mahābhārata.' Notwithstanding the traditional character and the gradual growth of the poem, Vyāsa has been supposed not only its author, but even the operation of collecting its component parts has been attributed to him, as it was he who, according to Hindu tradition, collected the Vedās and Purānās, and composed the Brahmasūtras of the Vedāntine school. But as these operations could not be executed by the same individual, it has long been acknowledged that the name of Vyāsa (implying *disposition*) does not signify a distinct historical person, but rather an allegorical character, including the important fact that the four great parts of the sacred canon were digested by the same orthodox body of the ancient Brahminical schools, by whom almost every branch of the traditional and scientific learning of the Hindus has been successively propagated and preserved. Hence a religious and priestly character prevails in the epic poetry of the Hindus ; in this sense the 'Akhyāna' is often styled a fifth 'Veda,' and the 'Rāmāyana,' as well as 'Mahābhārata,' are in fact considered as the 'Sāstra' of the Kshatriya caste, for whose recreation, encouragement, and instruction they were originally designed. Compared with the 'Rāmāyana' the 'Mahābhārata' is wanting in unity and internal coherence ; it is rather a collection of ancient epic poems, gathered round the central history of the Kurus and Pāndus : but for this very reason it far surpasses the former poem by a greater variety of pleasing scenes and attractive situations, particularly in its episodes, the characters of which are very often delineated with so peculiar a delicacy, and with so strongly marked an individuality, as to leave a powerful impression on the reader. Finally, and what is more essential, the 'Mahābhārata' may be looked upon as a most ample source of every kind of antiquarian lore, and as the only Sanskrit work, if we except the 'Annals of Kashmir,' by which a considerable quantity of the most valuable historical fragments has been preserved. The truth of this will be shown in a series of learned essays lately begun by Prof. Lassen (in 'Zeitschrift für die Kunde des Morgenlandes'). The great war itself, which on astronomical calculations has been supposed to have taken place during the 12th century B.C. (Works of Sir William Jones, iii., 213 ; vii., 77), is indubitably an historical event ; and as Pāndu (white), Krishna (black), Duryodhana, Dhritarāshtra, and other names are allegorical, Prof. Lassen acutely suggests, that the war might be the long and serious contest between the Brahminical tribes and the native occupants of the country. Leaving aside these questions, we only remark that although the 'Bhārata,' properly so called, is by no means contemporary with the events described in it, its pretensions to a very remote period of Hindu antiquity are sufficiently justified by internal evidence and the unanimous testimonies of subsequent writers. The poem is evidently of later date than the 'Rāmāyana,' but neither the precise time in which it was composed, nor even the epoch of its finally assuming its present shape, can yet be ascertained.

A complete edition in the original Sanskrit, carefully collated by learned Pundits with the best manuscripts in the library of the Sanscrit College of Calcutta, has been published by the Asiatic Society of Bengal, in four volumes royal 4to., with an index in a separate volume, the last of which was issued in 1839. A number of detached fragments and single stories of the 'Mahābhārata,' have been faithfully translated by Sir Charles Wilkins, Prof. Wilson, and Mr. Milman, such as 'The Churning of the Ocean,' the 'Story of Dushwanta' and 'Sacuntalā.' This last has also been issued in a most splendid form from the press of Mr. Austin, of Hertford, freely translated in prose and verse, by Monier Williams in 1855 ; it has also been translated into French and German ('Annals of Oriental Literature ; 'Oriental Quarterly Magazine,' 1825 ; 'Quarterly Review,' vol. xiv.). The following episodes also have appeared in the original Sanskrit : 1. 'Nala and Damayanti,' published by F. Bopp, Lond. 1819 ; Berlin, 1832. Translated into English verse by H. H. Milman, Oxford, 1835. 2. The 'Bhagavadgītā,' by A. W. Schlegel, Bonn, 1823. An English prose translation was published by Sir Charles Wilkins, London 1785. 3. 'Indralokāgamanam,'

'Hidimbabadha,' 'Brāhmavilāpa,' 'Sundas and Upasunda,' and Tilotamā,' by Bopp, Berlin, 1824. 4. 'Diluvium cum tribus aliis Mahābhārati prāstantissimis episodii,' by Bopp, Berlin, 1829.

MAHOGANY: ECONOMICAL USES. This wood was first known in England in 1724, when Dr. Gibbons, a physician residing in King Street, Covent Garden, received a few planks from his brother, a captain in the West India trade. After much trouble, occasioned by the wood being too hard for the tools generally used by carpenters and cabinet makers, a candle-box and a bureau were made, and excited much admiration for the beauty of the wood. The fact became known, more planks were procured, and the cabinet-maker employed realised a fortune by making articles of furniture in mahogany. From that year this wood began to supersede walnut and pear-tree in the houses of the rich.

The mahogany forests are chiefly in Cuba and Central America. The tree grows to so large a size, that logs of six or seven tons are frequently imported. The cost is chiefly made up of the expenses incident to the conveyance of such vast masses to the shipping ports, in countries where roads are few and the means of traction defective. The season for cutting commences in August. The men work in gangs of from fifty to a hundred each, under a *hunterman* to search out the best trees, and a *captain* to regulate operations. They determine on a sufficient number of trees to employ the whole gang during the season. Each tree is cut about ten or twelve feet from the ground, a stage being erected on which the men stand. The trunk is preferred for large timbers, but the branches for more beautiful grain, knots, curls, &c. The men live meanwhile in some sort of temporary village near a river, and construct a road from thence to the spot where the trees lie, often through dense forests of other kinds of wood, such as the bullet-tree, iron-wood, red-wood, and sapodilla. Their labour is exceedingly heavy, for many miles of road have often to be made, by clearing away the underwood with cutlasses, lopping down the trees with the axe, destroying the larger trunks by fire, levelling hillocks, and blasting rocky ground. By about December the roads are made: and the mahogany trunks are cut crosswise into logs, each of such size that a bullock-train can draw it. The largest log ever cut in Honduras is said to have been 17 feet long, 57 inches broad, 64 inches deep, and 15 tons weight; on account of its beauty and value it was left of unusually large size, and additional oxen were set apart to draw it. When reduced to logs by cross-cutting, the mahogany is brought from the round to the square shape, by the axe. These operations being finished by March, the two dry months of April and May are employed in dragging the timber to the river. The trucks employed require each seven pairs of oxen and two drivers; and the logs are placed upon them by being dragged up a temporary inclined platform. To avoid the great heat of the sun in that climate, the loading and carrying are conducted at night, by torchlight. Arrived at the river, the logs are set afloat; and when the rainy season of June has commenced, they are floated down to Belize or some other fort, the gangs rowing down in flat-bottomed canoes, and guiding the logs in their course.

When brought to England or any other market, the price varies extremely, being dependent partly on the size of the logs and partly on the beauty of the wood. When a log is fine enough to be cut up into broad and beautiful veneers, it will bring a high price. Some years ago Messrs. Broadwood, the eminent pianoforte manufacturers, gave a higher price than has ever been known before or since for three logs of mahogany: namely, 2000*l*. Each log was 15 feet long by about 38 inches square. When cut into veneers of an eighth of an inch, the wood was peculiarly beautiful, susceptible of receiving the highest polish; and when polished, it reflected the light in a very varied manner, like the surface of a crystal. The general figure of the grain resembled the ripple or small waves of water gently moved by the wind; and on this account the wood, which for twenty years was employed for veneering some of the more costly pianofortes, obtained in the factory the name of *ocean-wood*. In this special example, the wood was *Honduras* mahogany; but in the general state of the market the *Spanish* is a finer kind, and brings a higher price. As a sort of average, Spanish mahogany is in logs about 10 feet long by 20 to 26 inches square; while Honduras is 12 to 18 feet long, and from 2 to 4 feet square. Specimens of Honduras mahogany have come to market from which planks 7 feet in width could be cut. *African* mahogany twists more than Spanish or Honduras, and is inferior to them in most qualities except hardness. Mahogany warps less, and holds glue better, than most other kinds of wood, and on these accounts is much valued for cabinet work, besides its largeness of size and beauty of appearance.

From a paper read before the Society of Arts in 1859, by Mr. Leonard Wray, it appears that there are eight kinds of wood which are ranked 'first class' at Lloyd's as employed in shipbuilding; twenty others are ranked as 'second class,' including mahogany. The finest quality of mahogany is too costly to be used for the large timbers of ships, while the cheaper qualities are not good enough. That good mahogany is a magnificent wood for shipbuilding is, however, well known. A Spanish 80-gun ship, built of mahogany, was captured by the English in 1757; and her timbers, more than a century old, were found to be perfectly sound. Her Majesty's beautiful steam yacht, 'Victoria and Albert,' is built almost wholly of mahogany; and there is an increasing use of this kind of timber by shipbuilders.

ARTS AND SCI. DIV. VOL. V.

The uses of the mahogany tree for other purposes than its timber are too few to need description here.

MAIL (from the French *maille*), strictly "the mesh of a net," but applied in a collective view to defensive armour formed of iron rings or round meshes. Boyer, in his French dictionary, translates *maille* "a little iron ring." In the ancient armour the habergeon and hauberk were called coats of mail. [ARMOUR.] Mail or malle was also the name given to a bag or small sack, at first probably because made of net-work; since applied likewise to the portmanteau or portmanteau.

MAIM (in law, "mayhem") is an injury done to the body of a man by forcibly depriving him of the use of some member serviceable in fight, as a means either of defence or offence, and permanently disabling him from offering such an effectual resistance to further attacks upon his person as he otherwise might have done; as if a foot, hand, or finger, or a joint of the foot or hand, be struck off or made crooked or weakened, or if a bone of the head be removed, or a fore-tooth broken or displaced, or if an eye be beaten out, or if any other bodily injury be inflicted whereby the party is rendered less capable of making a vigorous defence. But destruction of a jaw-tooth, of an ear, or of the nose, or of other members, the loss of which does not interfere with the means of defence or offence, does not amount to mayhem. The distinction however is by statutory alterations in the law rendered of little importance.

Mayhem was formerly punished by inflicting the same privation upon the offender which he had caused to the party maimed. It was afterwards punishable by fine and imprisonment, as an aggravated trespass. But now, by 7 Wm. IV. and 1 Vict., c. 85, to stab, cut, or wound, if with intent to murder, is a capital felony, and if with intent to maim, disfigure, or disable, is a felony punishable by transportation for life, or for not less than 15 years, (for which penal servitude is now substituted) or by imprisonment not exceeding three years. The statute 9 & 10 Vict., c. 25, makes it a felony to maim by the malicious explosion of gunpowder or other explosive substance; so also by the same statute it is a felony maliciously to cause any gunpowder or explosive substance to explode, or to send to any person any dangerous or noxious thing, or to throw any corrosive fluid or other destructive substance at any person with intent (*inter alia*) to maim, and these offences are now punishable by penal servitude for life, or imprisonment for three years.

Concurrently with these proceedings in the name of the crown, for the purposes of public justice, the party injured is entitled to compensation in the shape of damages, to be recovered in an action of trespass; and where the damages found by the jury are not commensurate to the injury sustained, the court may increase them upon inspection of the mayhem.

MAINTENANCE is defined to be when a man maintains a suit or quarrel to the disturbance or hindrance of right; and if he who maintains another is to have by agreement part of the land or debt, &c. in suit, it is called Champerty. Maintenance was an offence at common law, and has also been the subject of several statutes. By the 32 Hen. VIII., c. 9, no person shall bargain, buy or sell, or by any means obtain any pretended rights or titles to any lands, unless he who bargains or sells, or his ancestors, or they by whom he claims the same, have been in possession thereof, or of the reversion or remainder thereof, or taken the rents and profits thereof, by the space of a year next before the bargain or sale, on pain of the seller forfeiting the whole value of the lands so bargained or sold, and the buyer, knowing the same, also forfeiting the value of such lands. The professed object of the statute was to prevent the inquietness, oppression, and vexation which the preamble mentions as the consequence of the buying of titles and pretended rights of persons not being in possession of the lands sold. By the 8 & 9 Vict. c. 106, rights of entry may however be assigned or charged by deed.

A man may assign his interest in a debt after he has instituted a suit for its recovery, and such assignment of itself is not maintenance. But if the assignment be made on condition that the assignee prosecute the suit, or if the assignee give the assignor any indemnity against the costs of the suit, already incurred or to be incurred, this makes it maintenance.

(Comyn's *Digest*, 'Maintenance.')

MAINTENANCE, SEPARATE. [SETTLEMENT.]

MAIZE, or *Indian Corn*, is a plant commonly cultivated in the warmer parts of the world, where it answers a purpose similar to that of wheat in more northern countries. It is the *Zea Mays* of botanists, a monococious grass, of vigorous growth, with stems not more than two feet high in some varieties, and reaching the height of eight or even ten feet in others. The leaves are broad, and hang down from large rough sheaths which surround the stem. The male flowers grow in loose, terminal, compound racemes, standing clear of the leaves; the females are arranged in numerous rows on a spike, which is wrapped round by several folds of sheathing bracts, which press upon the grains and give them the flattened figure they eventually acquire when ripe. Each grain has a long thread-like style, which projects beyond the enveloping sheaths; and as there are some hundreds of them upon each spike, the whole form a long tassel, which looks as if made of silk. The ripe grains are regularly arrayed one over the other in rows, are compressed at the sides, flattened at the apex, and of various colours. Their most common colour is pale yellow; some are white,

F F

some party-coloured, and there are varieties with blood red and even purple grains. A plant generally bears two full ears, the grains of which vary greatly in number: some of the largest ears in America contain at least 800 grains.

This plant in its wild state is met with in Paraguay, according to Auguste de St. Hilaire. It was also found on the continent of North America by the Europeans on their arrival there.

It seems that there is a particular line on the continent of Europe north of which the maize does not thrive. To the south of this line, which passes through Nancy, formerly the capital of Lorraine in France, it has in a great measure superseded wheat and rye as the common produce of the land. The bread made from maize is not so palatable as wheat or rye bread; but by mixing it in certain proportions with wheat it makes a very pleasant food. In the United States of North America, Indian corn forms almost the only bread eaten by many of the people; and in the slave-states it is the only bread that the negroes eat. It is not however in the shape of baked bread that maize is most generally used in Europe, but in boiled messes and soups, as peas are with us: it is not only the ripe grain which is eaten, but the ear in every state, from that of a green vegetable to an unripe corn. It is boiled, stewed, and baked: it is a substitute for cabbage or green-peas in its early stage; and is used in some way or other to its complete maturity. Nothing can be better than ripe maize to fatten hogs or poultry with; and the young stem cut down quite green gives one of the best and most abundant varieties of green food for cattle.

A plant which gives such a return cannot be expected to ripen its grains in poor land, or without attentive cultivation. The land must be naturally fertile, or made so by art; it must be well prepared to receive the seed, and sufficient manure must be given to recruit it. A light, moist, and warm soil suits this plant best. It thrives well on land broken up from grass, as is the case with most plants. As it is always sown in rows, and the plants thinned to a considerable distance, the intervals may easily be ploughed, or stirred with the horse-hoe, by which means the weeds are kept down, and the earth fertilised by exposure to the air. The seed should be taken from the largest and best formed ears; those at the end should be rejected, as less perfect. They should not be taken off until they are wanted for sowing, and then steeped in water to soften them. If the seed were steeped in brine and dried with quicklime, as is usually done with wheat, it might probably be advantageous, as this grain is subject to smut and brand as well as wheat; but this is not often done. The time for sowing maize in the south of France is the month of April; farther north it is sown later for fear of frost, which would entirely destroy the plant on its first appearance above ground: this is one of the reasons why it could not safely be sown in England before the middle or end of May, and it could scarcely be expected to ripen its seeds before the winter's frost set in.

The distance between the rows of maize varies from two to four feet. In good ground the latter distance has produced the heaviest crop. The seed is sometimes sown in the furrow after the plough, and sometimes put in with a dibble. The latter seems the best way, and, as the rows are wide and the seeds need not be put in nearer than a foot apart in the rows, an acre will be soon dibbled by hand. Two or three inches deep is sufficient to make the seed germinate readily. In warm moist climates the plant is very soon above ground. In fine weather, and when the seed has been steeped, it will be above ground in five or six days. When the plants are three or four inches out of the ground, and no frost is feared, they are thinned out to two feet apart, and in very rich soils three feet is better. In this case three or four ears may be expected to ripen on each stalk. In thin soils on a retentive subsoil the earth is raised in ridges, or, what is better, in mounds, by crossing the ridges with the plough, and three or four seeds are put into each hillock, which are two or three feet apart. As the plants rise, only one, or at most two are left in each hillock, and the earth is carefully moulded up to the stems; thus a deep dry bed is provided for the plant, and there is sufficient moisture from the impervious subsoil. This method might perhaps be adopted with advantage in England, in experiments on maize, where the situation admits of its cultivation. Maize, however sown, must be repeatedly hoed. At the first hoeing the plants which are too close are pulled up, and where there is a deficiency they are planted in: at least, this is the practice in Europe; but in America the general practice is to plant fresh seeds in the vacant places. When the plants are a foot high there is a second hoeing, the weeds are then cut up, and some earth is drawn towards the plants and raised around the stems. The reason of this is, that there are several joints very near each other at the bottom of the stem, and from each of these fibres strike out into the soil which is brought into contact with it, and form additional roots to the plant, as they do from the crown of the roots of wheat. When the flowers are ready to expand, a third hoeing is given, to kill weeds and open the surface of the soil slightly. The earth which is raised around the stems should be flattened a little at top, and even slightly hollowed out near the stem, to collect the dews and rains in dry seasons. If any tillers or shoots appear from the bottom of the stem they should be carefully removed, as they diminish the nourishment which should go to the main stem. A fourth hoeing and earthing up, at the time when the seed begins to swell, is useful, but seldom given, for fear of unnecessary expense. In many countries they sow or plant various vegetables in

the intervals between the rows of maize, of which the most advantageous are turnips and cabbages, which may be sown or planted between the maize, after the last hoeing. French beans, except they be dwarfs, are not so proper, as they shade the maize and prevent its maturity. In warm climates cucumbers and melons are often raised there. In Carolina, where they hoe their maize only twice, a running weed springs up rapidly, which is much relished by cattle, and is cut several times before winter.

The time of flowering is very critical for the maize: a cold damp atmosphere may make a great part of the crop fail. In situations where this is to be feared, it is safe to sow maize at several times, with a week's interval: thus the risk is divided, and it is not so likely that the whole crop will be in flower in ungenial weather.

The male flowers, just as they expand, are excellent food for cattle; and it is usual in many places to cut off a great portion of them for this purpose. If it be done judiciously, there is no danger, provided a sufficient number of male flowers be left to impregnate the females: one in a square of about fifteen or twenty feet is thought sufficient. After the seed is set it is customary, in many places, to cut off the whole top of the stem, with the upper leaves, and give them to the cattle; but this is by no means to be recommended: the wound thus made bleeds, and much of the sap is lost. Besides, the upper leaves serve to elaborate the sap and assist its circulation; they should therefore be left on as long as they are green, and other food found for the cattle.

All plants which stand too close or have no ears upon them should be pulled up and given to the cows, to give air to the rest; all those also that are very late and have abortive ears should be taken up, as they would at all events not ripen their seed. The young ear is preserved as a pickle, like young cucumbers: when a little advanced it is roasted on the coals, or before the fire, and is pleasant to eat: in the green state, when the grains are still soft and milky, it is boiled, and used as a vegetable, and is considered a delicacy.

Maize is subject to diseases similar to those of wheat and other grain; and it is supposed, as observed before, that the steeping and liming may prevent them in a great measure.

When the maize is fully ripe, which it is not until the sheath of the ear opens and appears quite dead, the ears are twisted off by hand and laid in a dry place; they are turned occasionally that the sheath may not become musty, and are then stored in a dry place: the seed keeps better so than when it is separated. The taking off the seeds from the ear is a laborious operation; it may be done by the flail, but is most easily accomplished by an old blunt sword or iron hoop fixed over a tub. The ears are rubbed hard over this edge, and the seeds fall into the tub. They have a simple machine in America, which does the work quickly. The core or rachis is only fit for burning in the oven. The leaves are gathered for fodder a short time before the ears are pulled. In America and in Italy they stuff mattresses with the dry sheath, which makes a cool and elastic bed.

All animals are fond of maize, especially horses, pigs, and poultry; it gives the flesh of the two last a peculiarly fine flavour. The most profitable way to use maize in fattening animals is to grind it into meal, and mix it with warm water into a pottage; and, for horses, to soak it twenty-four hours in water before they are fed with it. In the dry state it is so hard that it wears their teeth, and in young horses is apt to produce blindness by the exertion of the muscles of the jaw in chewing it.

One of the most important uses of maize in Europe is to sow it thick, to be cut green as food for cows, oxen, and sheep. In a proper climate there is no plant which gives so great a mass of green food as maize. The produce is most abundant and nutritive. The largest varieties should be chosen. The seed may be sown in drills in April, and in September a crop might be mown, which would give admirable fodder for every kind of cattle. It is said to exhaust the land; but what will not exhaust it, more or less, which gives much nourishment? Maize will well repay the manure which may be required to restore the humus it has consumed. If it is sown early, a second crop may be raised the same year; for it does not spring up again, like grass, after being cut. Where the land admits of irrigation, the growth of the maize is most rapid and luxuriant. The time to cut it is when the male flowers are just appearing out of the sheath in which they are enveloped in the early stage of their growth. It may be dried into hay, and will keep good for a couple of years; but in this state it must be bruised or soaked when given to cattle, as the stems get very hard in drying; they may however be cut, as the cane-tops are in the sugar-plantations.

MAJOR (Latin), *Greater*, in music, a term applicable to the imperfect concords, but chiefly to the interval of the 3rd. It is also used to distinguish the mode which takes a major or sharp 3rd, from that having a minor or flat one. The *major* mode has always a greater 3rd—that is, a 3rd consisting of two tones; and the minor mode has always a minor 3rd—that is, a 3rd consisting of a tone and a semitone. [KEY; MODE; THIRD.]

MAJOR, a field-officer next in rank below a lieutenant-colonel, and immediately superior to the captains of troops in a regiment of calvary, or to the captains of companies in a battalion of infantry. His duty is to superintend the exercises of the regiment or battalion, and, on parade or in action, to carry into effect the orders of the colonel. The major

has also to regulate the distribution of the officers and men for the performance of any particular service; and he has a temporary charge of the effects appertaining to any individual of the corps, in the event of the absence or death of such individual.

This class of field-officers does not appear to have existed before the beginning of the 17th century; and, at first, such officers had the title of *serjeants-major*, a designation borne at an earlier time by a class corresponding to that of the present majors-general of an army. (Grose, vol. i. p. 243.)

No mention is made of either lieutenants-colonel or majors as field-officers in the account of Queen Elizabeth's army in Ireland (1600). But Ward, in his 'Animadversions of Warre' (1639), has given a description of the duties of the latter class, under the name of *serjeants-major*, from which it appears that those duties were then nearly the same as are exercised by the present majors of regiments. They are stated to consist in receiving the orders from the general commanding the army; in conveying them to the colonel of the regiment, and subsequently in transmitting them to the officers of the companies; also, in superintending the distribution of ammunition to the troops, and in visiting the guard by day or night.

A brigade-major is a staff-officer who performs for a brigade, or in a garrison, duties corresponding to those of a major in a regiment or battalion.

A serjeant-major of a regiment is a non-commissioned officer, who in general superintends the military exercises of the soldiers: on parade, he has the care of dressing the line.

MAJOR-GENERAL. [GENERAL.]

MALAMIC ACID. [MALIC ACID.]

MALAMIDE. [MALIC ACID.]

MALANILIC ACID. [MALIC ACID.]

MALATES. [MALIC ACID.]

MALE FERN, the rhizoma, incorrectly termed root, of the *Nephrodium Filix Mas* (Richard), *Aspidium Filix Mas* (Smith), has been celebrated from ancient times as an anthelmintic. The rootstock of young plants should be collected in spring or summer, and a fresh supply obtained every year, as a change occurs in the part a few months after being collected. It should be quickly dried, and preserved in glass or earthenware vessels in a dry place. The interior should exhibit a greenish colour, and possess a disagreeable odour, with a bitter harsh astringent taste. Male fern buds have the same properties.

The rhizoma contains a volatile oil, which may be extracted by sulphuric ether; resin, tannin, uncrystallisable sugar, starch, and woody fibre. The oil, which is of two distinct kinds, one pure, and the other united with resin and an extractive, is the active principle. Formerly a powder of the whole substance was administered, but as the dose of this is bulky, Peschier has recommended pills of ethereal extract, which are found to be very efficacious against that kind of tape-worm which is denominated the *Bothriocephalus latus*, or broad tape-worm. It is scarcely possessed of any power over the *Tænia solium*. The former infests the small intestines of the inhabitants of Poland, Russia, Switzerland, and some districts of France, in all which countries the male fern has a high reputation as a remedy; but it is not much valued as an anthelmintic in Britain, where the broad tape-worm is nearly unknown.

MALEATES. [MALEIC ACID.]

MALEIC ACID ($C_4H_4O_4$). An organic acid, prepared by the dry distillation of malic acid. It crystallises in oblique rhomboidal prisms, which are colourless and inodorous, and possess a nauseous but acid taste. They are soluble in water, alcohol, and ether, and the solution reddens litmus. Heated strongly, maleic acid is converted into anhydrous maleic acid ($C_4H_2O_4$). When long boiled it is converted into fumaric acid, which is isomeric with maleic acid; and finally, when the lime salt is placed in contact with putrid cheese, it is converted into succinic acid. It unites with bases to form *maleates*.

MALIC ACID ($C_4H_4O_5, 2HO$) was discovered in 1785 by Scheele. It received its name from having been first obtained from the juice of apples, in which it exists in considerable quantity, and also, as has been since ascertained, in various other fruits, as cherries, raspberries, strawberries, in house-leek, and the berries of the sorbus or mountain-ash. Mr. Donovan, who procured it from the last mentioned source, obtained it of so great purity that he supposed it to be a new and peculiar acid, which he called sorbic acid; but it has since been proved to be identical with the malic. A mucilaginous substance which accompanies the acid obtained from apples prevents its properties from being perfectly and readily developed.

Various processes have been proposed for procuring this acid, and they are generally complicated: the following, proposed by Liebig, is perhaps as good as any: Add carbonate of lime, but not to perfect saturation, to the expressed juice of the mountain ash; the solution is to be decomposed by nitrate of lead, which precipitates malate of lead; this, after washing with cold water, is to be heated with boiling dilute sulphuric acid, and the resulting mass with sulphide of barium, by which there are formed sulphide of lead and sulphate of baryta, while the clear liquor contains malic acid, to which ammonia is then added to convert it into bimalate of ammonia, which readily crystallises; this salt is to be precipitated by acetate of lead, and the resulting malate of lead decomposed by hydrosulphuric acid; the clear liquor, separated

from the sulphide of lead, being evaporated by a gentle heat, yields crystals of malic acid, which are not however regular in their form. Malic acid is colourless, inodorous, very sour to the taste, and acts strongly on vegetable blues; in a moist air it is deliquescent; it is very soluble both in water and alcohol. Nitric acid converts it into oxalic acid. Its saline compounds are called malates, some of which exist in nature, as for example, bimalate of lime in the juice of the houseleek.

When malic acid is subjected to a heat of about 350° Fahr., it is decomposed into water and two isomeric pyro-acids, the maleic and the fumaric acids.

The malates are not an important class of salts. We shall mention the general properties of a few of them. They may be divided into two classes, namely:—the neutral malates which have the formula $C_4H_4O_5, 2MO$, and the bimalates consisting of $C_4H_4O_5, MO HO$.

Malate of ammonia is a deliquescent salt, but the bimalate is crystallisable, unalterable in the air, and insoluble in alcohol. Malate of potash is a deliquescent mass; the bimalate forms crystals which are unalterable in the air and insoluble in alcohol. Malate of soda is a deliquescent mass, the supermalate crystallises. Malate of lime is sparingly soluble in water, requiring 147 parts of it cold, and 65 when boiling: the hot solution deposits crystalline grains on cooling. It is stated to be more soluble in some saline solutions than in pure water; the bimalate occurs in houseleek and some varieties of *sedum*; it may be formed by adding acid to the neutral salt; by exposure to heat it dries as a transparent varnish, which distinguishes it from other salts of lime and vegetable acids. It is soluble in water, but insoluble in alcohol. Malate of magnesia yields crystals which are unalterable in the air and are soluble in twenty-eight parts of water; with excess of acid, a gummy deliquescent saline mass is formed. Malate of baryta both neutral and acidulous, is soluble and gummy; an insoluble subsalt may also be formed. Malate of strontia is gummy and deliquescent, the acid salt is but slightly soluble, but more so in hot than in cold water; the hot solution deposits crystals on cooling. Of the metallic malates we shall state the properties of a few:—Zinc forms three different compounds with this acid: the neutral malate crystallises in short four-sided prisms; it is soluble in 55 parts of cold water; by boiling water it is decomposed into a supersalt which dissolves, and a subsalt which is precipitated; bimalate of zinc crystallises in large regular octohedrons; the submalate is an insoluble white powder. Malate of peroxide of iron is a reddish brown-coloured deliquescent mass soluble both in water and alcohol. Malate of copper, whether neutral or acidulous, dries so as to form a green varnish which is unalterable in the air. The malate of silver is a gummy mass, but the bimalate is a crystallisable salt, which readily separates as such from solution in water. Malate of lead is nearly insoluble in cold water, but dissolves in boiling water, and the solution on cooling deposits brilliant white crystalline scales of this salt.

Malic acid forms two amides, namely, *Malamic acid* ($C_4H_4O_4, NH_2HO$) isomeric with aspartic acid, and *malamide* ($C_4H_4N_2O_4$) isomeric with asparagin. [ASPARAGIN.]

The following compounds are closely related to these amides:

Phenyl-malamide or malanilide . . . $C_8H_6(C_{12}H_5)N_2O_6$

Phenyl-malimide or malanile . . . $C_8H_4(C_{12}H_5)NO_6$

Phenyl-malamic acid or malanilic acid . $C_8H_6(C_{12}H_5)NO_5$

MALICIOUS INJURIES TO PROPERTY. At common law-mischief perpetrated with whatever motive against the property of another was not punishable criminally, unless the act amounted to felony, or was accompanied with a breach of the peace, or affected the public convenience. In other cases the offender was liable only to an action for damages at the suit of the party injured. But the legislature has, at different times, interposed to repress, by penal enactments, injuries to private property of an aggravated nature, committed with the malicious intention of injuring the owner of such property. The different statutory provisions against mischievous acts done wilfully and maliciously were modified, as well as consolidated, by 7 & 8 Geo. IV., c. 30,* which also contains a provision rendering it immaterial whether the malice of the offender be against the owner of the property or otherwise.

By the third section of that statute it is made felony punishable by transportation for life or not less than seven years, or by imprisonment not exceeding four years, with or without whipping in the case of a male, to cut, break or destroy, or damage with intent to destroy or to render useless, any goods or articles of silk, woollen, or linen, or of articles in which any of those materials are mixed, or any frame-work-knitted piece, stocking, hose, or lace, in any stage of manufacture; to cut, break or destroy, or render useless warps or shoots of silk, woollen, linen or cotton, or of any of those materials mixed with each other or with any other material; or looms, frames, machines, engines, racks, tackles, or implements prepared for or employed in manufacturing or preparing such goods; or to enter by force into any place with intent to commit any of those offences. By section 4, it is made felony punishable by transportation for seven years, or imprisonment not

* A bill has been introduced into Parliament, in the present session (1860), to consolidate the whole of the existing laws relating to malicious injuries to property.

exceeding two years, with or without whipping in case of a male, to cut, break or destroy, or damage with intent to destroy or render useless, threshing-machines, or machines or engines prepared for or employed in manufactures, except those manufactures, &c. injuries to which are more severely punishable under the 3rd section.

By the 6th and 7th sections it is made felony punishable by transportation for seven years, or by imprisonment not exceeding two years, with or without whipping in the case of a male, to cause water to be conveyed into mines, or subterranean passages communicating therewith, or pull down, fill up, or obstruct air-ways, water-ways, drains, pits, levels, or shafts, with intent to destroy, damage, or hinder or delay the working of mines; or maliciously to pull down, or destroy, or damage with intent to destroy or render useless, steam-engines, or engines for making, draining, or working mines, or staiths, buildings, or erections used in conducting the business of mines or bridges, waggon-ways, or trunks for conveying minerals from mines, whether completed or unfinished. By sect. 12 it is made felony punishable by transportation for life or not less than seven years, or by imprisonment not exceeding four years, with or without whipping in the case of a male, to break down or cut down sea-banks or sea-walls, or the banks or walls of rivers, canals, or marshes, whereby lands are overflowed or damaged, or in danger of being so; to throw down, level, or destroy locks, sluices, floodgates, or works on navigable rivers or canals. And by the same section it is made felony punishable by transportation for seven years, or by imprisonment not exceeding two years, with or without whipping in the case of a male, to cut off, draw up, or remove piles, chalk, or other materials fixed in the ground and used for securing sea-banks or sea-walls, or the banks or walls of rivers, canals, or marshes, or to open or draw up flood-gates, or to do other injury or mischief to navigable rivers or canals, with intent or so as to obstruct or prevent the carrying on or completing or maintaining the navigation.

It is made felony, punishable by transportation for life, or not less than seven years, or by imprisonment not exceeding four years, with or without whipping in the case of a male, by the 13th section, to pull down or destroy public bridges, or to do any injury with intent or so as to render them dangerous or impassable; and by the 18th section, to cut or destroy hop-bines growing on poles in any hop-plantation. But now (by 7 Wm. IV. and 1 Vic., c. 90, s. 2) the punishment of the latter offence is made transportation not exceeding 15 years and not less than 10 years, or imprisonment not exceeding three. By 7 & 8 Geo. IV., c. 30, s. 14, it is a misdemeanor punishable accordingly [MISDEMEANOR] to throw down, level, or destroy turnpike-gates, or walls, chains, rails, posts, bars, or fences belonging to turnpike-gates set up to prevent passengers passing by without paying toll, or houses, buildings, or weighing-machines for the collection, ascertainment, or security of toll. The 15th section makes it a misdemeanor punishable by transportation for seven years, or by imprisonment not exceeding two years, with or without whipping in the case of a male, to break down or destroy dams of fish-ponds, or of water being private property, or in which is a private right of fishing, with intent to take or destroy fish, or so as thereby to cause the loss or destruction of fish, or to put lime or noxious materials in ponds with intent to destroy fish, or to break down or destroy dams of mill-ponds. By section 16 it is made felony to kill, maim, or wound cattle; but the punishment is reduced by 7 Will. IV. and 1 Vic., c. 90, s. 2, to transportation not exceeding 15 years and not less than 10, or to imprisonment not exceeding three. The provisions of this statute (7 & 8 Geo. IV., c. 30) relating to the destruction of trees, plants, &c. have been already noticed. [LARCENY.]

By section 17 it was made felony punishable by transportation for seven years, or by imprisonment not exceeding two, with or without whipping in the case of a male, to set fire to any crop of corn, grain, or pulse, whether standing or cut down, or to any part of a wood, coppice, or plantation, or to any heath, gorse, furze, or fern, and by 7 Wm. IV. and 1 Vic., c. 89, it is made felony punishable by transportation for life or not less than 15 years, or by imprisonment not exceeding three (sect. 10), to set fire to any stack of corn, grain, pulse, tares, straw, haulm, stubble, furze, heath, fern, hay, turf, peat, coals, charcoal, or any steer of wood, or (sect. 11) to set fire to any mine of coal or cannel coal.

The enactments in this statute with respect to the burning of houses, &c. [ARSON] have been repealed; and now by 7 Wm. IV. and 1 Vic., c. 89, s. 2, it is felony punishable by death to set fire to a dwelling-house, any person being therein; and by s. 3 it is felony punishable by transportation for life, or not less than 15 years, or by imprisonment not exceeding three, to set fire to a church or chapel, or a chapel for the religious worship of dissenters, or to a house, stable, coach-house, outhouse, warehouse, office, shop, mill, malthouse, hop-oast, barn, or granary, or to a building used in carrying on trade or manufacture, whether in the possession of the offender or of any other person, with intent to injure or defraud any person. By the 7 & 8 Vict., c. 62, the last-mentioned provisions were extended to the burning of farm buildings, and of farming produce therein; and by the 9 & 10 Vict., c. 25, s. 7, the attempting to set fire to any building, vessel, or mine, or to any stack or steer, or to any vegetable produce, of such kind, and with such intent that the offence, if complete, would be felony punishable by transportation for life, is also made a felony

punishable by transportation not exceeding 15 years, or imprisonment not exceeding two years.

The stat. 14 & 15 Vict., c. 19, makes the setting fire to any station, engine-house, warehouse, or other building belonging to any railway, dock, canal, or other navigation, a felony punishable by transportation for life, or not less than seven years, or imprisonment not exceeding three years; and the same statute also makes the setting fire to goods or chattels in any building, the setting fire to which is felony, itself a felony, punishable by transportation not exceeding ten nor less than seven years, or imprisonment not exceeding three years.

For the protection of shipping against malicious mischief several statutory provisions have been made. By the 12 Geo. III., c. 24, the wilful and malicious burning or destroying of any of the king's ships of war, or arsenals, dockyards, victualling offices, or military, naval, or victualling stores, &c., is made a capital felony. By 1 & 2 Geo. IV., c. 75, s. 11, it is felony punishable by transportation for seven years, or imprisonment for any number of years, to cut away, cast adrift, alter, deface, sink, or destroy, or do any act with intent to cut away, cast adrift, remove, alter, deface, sink, or destroy, or injure or conceal buoys, buoy-ropes, or marks belonging to ships or vessels, whether in distress or otherwise. By 7 Geo. IV., c. 30, s. 10, it is made felony punishable by transportation for seven years, or by imprisonment not exceeding two, with or without whipping in the case of a male, to damage otherwise than by fire (which offence had been made capital by s. 9) ships or vessels complete or unfinished, with intent to destroy them or to render them useless.

By 7 Wm. IV. and 1 Vic., c. 89, s. 5, it is made felony punishable by death to exhibit false lights or signals with intent to bring any ship or vessel into danger, or to do any thing tending to the immediate loss or destruction of ships or vessels in distress. And by s. 6 it is made felony punishable by transportation for life, or not less than 15 years, or by imprisonment not exceeding three years, to set fire to, cast away, or destroy ships or vessels, with intent to prejudice owners or part-owners of vessels or goods, or underwriters on ships, goods, or freight. And by the 4th sect. it is made felony punishable by death, to set fire to, cast away, or destroy any ship or vessel, either with intent to murder any person, or whereby the life of any person shall be endangered.

It is to be observed, with reference to the punishment for these offences, that penal servitude has been substituted for transportation. Malicious injuries to works of art, &c., in any museum or repository, or to pictures, statues, monuments, or painted glass, in any church or chapel, is, by the 8 & 9 Vict., c. 44, a misdemeanor punishable by imprisonment not exceeding six months, and if a male by whipping; and by the 17 & 18 Vict., c. 33, this provision is extended to public statues within the metropolitan police district.

Besides the criminal responsibility thus created in respect of the acts of spoliation above enumerated, the legislature has given summary relief to persons whose property has been subject to petty but wilful aggressions. Under the 7 & 8 Geo. IV., c. 30, s. 24, persons wilfully or maliciously committing damage, injury, or spoil, to or upon real or personal property, for which no remedy or punishment is specially provided by that act, are, on conviction before a justice of the peace, to forfeit and pay such sum of money as shall appear to him a reasonable compensation for the damage, injury, or spoil committed, not exceeding 5*l.*, to be paid, in the case of private property, to the party aggrieved, except where such party is examined in proof of the offence; and in such cases, or in the case of property of a public nature, or wherein any public right is concerned, the money is to be applied towards the county-rate or borough-rate; and if such sums of money together with costs (if ordered) are not paid either immediately or within such period as the justice may appoint, the justice may commit the offender to the common jail or house of correction, to be kept to hard labour for any term not exceeding two calendar months, unless such sum and costs be sooner paid. This enactment does not extend to any case where the party trespassing acted under a fair and reasonable supposition that he had a right to do the act complained of, or to any trespass, not being wilful and malicious, committed in hunting, fishing, or in the pursuit of game.

By the 28th section any person found committing any offence against this act, whether punishable upon indictment or upon summary conviction, may be immediately apprehended without a warrant, by any peace-officer, or the owner of the property injured, or his servant, or any person authorised by him, and forthwith taken before some neighbouring justice of the peace.

These summary proceedings before magistrates must be commenced within three calendar months from the commission of the offence.

The provisions of the law of France with respect to malicious injuries to property are to be found in the 3rd section of liv. iii. of the Code Pénal, entitled 'Destructions, Dégradations, Dommages.' Capital punishment is denounced only against those who set fire to buildings, ships, warehouses, wood-yards (chantiers), forests, underwoods, or crops growing or cut down, or to any combustible matter placed so as to communicate fire thereto. Minor offences in forests are provided for by titre 12 of the Code Forestier.

MALINGERING. [FEIGNED DISEASES.]

MALLEABILITY, a property by virtue of which certain bodies, especially some of the metals, are capable, although in very different

degrees, of being beaten out under the hammer (*malleus*, Lat.), or laminated between rollers. The following table represents the order of malleability:—

Gold.	Iron.
Silver.	Tin.
Copper.	Lead.
Platinum.	Cadmium.
Palladium.	Nickel.
Aluminum.	Cobalt.
Zinc.	

Gold is usually cited as an extreme case of malleability. It is beaten to the 290,000th part of an inch in thickness, and often much thinner than this, even to the 367,650th of an inch, or about 1200 times thinner than ordinary printing paper, and even this is not the limit of malleability, although there are practical difficulties in the way of further reduction. Comparing equal weights of gold and silver, it will be found that silver can be made to cover a larger surface than gold, so that silver is really more malleable than gold, although the leaf cannot be beaten out so thin. The metals lithium, potassium, and sodium, as well as frozen mercury, admit of being extended under the hammer.

In the production of sheet-metal, the hammer has been to a great extent superseded by rollers. Iron, steel, and copper, are best rolled red-hot; zinc is most malleable between 300° and 400°; most of the other metals and alloys are rolled in the cold state. The rolling-mill performs its work in a more uniform and gradual manner than the hammer, and at the same time develops to the utmost the hardness, tenacity, elasticity, and ductility of such metals and alloys as admit of being rolled. During the process, the condensation is such that brittleness would be produced unless the process of annealing were resorted to at intervals. In rolling the thinnest sheets of metal, a number of them are often sent through the rollers at the same time. In some cases, gold and silver leaf for example, the metals are rolled as thin as they will economically admit of, after which the hammer is resorted to. Leaf iron has been rolled into sheets, the 2500th of an inch in thickness, and a square inch of the leaf weighed only three-quarters of a grain.

The difference between malleability and ductility is noticed under DUCTILITY. In both processes the particles seem to glide along each other's surface, and "the external layers of the metals are retarded or kept back, as it were, in a wave, whilst the central stream or substance continues its course at a somewhat quicker rate. The necessity for annealing occurs, when the compression and sliding have arrived at the limit of cohesion; beyond this the parts would tear asunder, and produce such of the internal cracks and seams met with in sheet metal and wire, as are not due to original flaws and air-bubbles which have become proportionably elongated in the course of the manufacture of these materials." Holtzapffel's 'Mechanical Manipulation.'

MALT; MALTING. Malt is made from all kinds of grain and from rice, but in England almost always from barley, for the use of brewers and distillers. It consists of grain which has become sweet and more soluble in water from the conversion of its starch into sugar by artificial germination to a certain extent, after which the process is stopped by the application of heat. The barley is steeped in cold water for a period which (as regulated by law) must not be less than 40 hours; but beyond that period the steeping may be continued as long as is thought proper. Here it imbibes moisture, and increases in bulk; at the same time a quantity of carbonic acid is emitted, and a part of the substance of the barley is dissolved by the steep-water. The proportion of water imbibed depends partly upon the barley, and partly on the length of time that it is steeped. From the average of a good many trials, it appears that the medium increase is about 47 per cent. in weight, and 20 per cent. in bulk. The carbonic acid emitted while the barley is in the steep is inconsiderable; and it is probable, from the experiments of Saussure, that it owes its formation, at least in part, to the oxygen held in solution by the steep-water. The steep-water gradually acquires a yellow colour. The quantity of matter which it holds in solution varies from $\frac{1}{50}$ th to $\frac{1}{100}$ th of the weight of barley. This extractive matter is obviously derived from the husk of the barley, and is that substance to which the barley owes its colour. Accordingly grain becomes much paler by steeping.

After the grain has remained a sufficient time in the steep, the water is drained off, and the barley thrown out of the cistern upon the malt-floor, where it is formed into a heap called the *couch*, about 16 inches deep. In this situation it is allowed to remain about 26 hours. It is then turned by means of wooden shovels, and diminished a little in depth. This turning is repeated twice a day or oftener, and the grain is spread thinner and thinner, till at last its depth does not exceed a few inches. When placed in a couch, it begins gradually to absorb oxygen from the atmosphere, and to convert it into carbonic acid, at first very slowly, but afterwards more rapidly. The temperature, at first the same with that of the external air, begins slowly to increase; and in about 96 hours the grain is at an average about 10° hotter than the surrounding atmosphere. At this time the grain, which had become dry on the surface, becomes again so moist that it will wet the hand, and exhales at the same time an agreeable odour, not unlike that of apples. The appearance of this moisture is called *sweating*. A small

portion of alcohol appears to be volatilised at this period. The great object of the maltster is to keep the temperature from becoming excessive, which is effected by frequent turning. The temperature which it is wished to preserve varies from 55° to 62°, according to the different modes of malting pursued.

At the time of the sweating, the roots of the grains begin to appear, at first like a small white prominence at the bottom of each seed, which soon divides itself into three rootlets, and increases in length with very great rapidity, unless checked by turning the malt. About a day after the sprouting of the roots, the rudiments of the future stem, called *acrospire*, may be seen to lengthen. It rises from the same extremity of the seed with the root, and advancing within the husk, at last issues from the opposite end; but the process of malting is stopped before it has made such progress. As the acrospire shoots along the grain, the appearance of the kernel, or mealy part of the corn, undergoes a considerable change. The glutinous and mucilaginous matter is taken up and removed, the colour becomes white, and the texture so loose that it crumbles to powder between the fingers. The object of malting is to produce this change: when it is accomplished, which takes place when the acrospire has come near to the end of the seed, the process is stopped by drying the malt upon the kiln. The temperature at first does not exceed 90°; but it is raised very slowly up to 140° or higher, according to circumstances. The malt is then cleared, to separate the rootlets, which are considered injurious.

Barley, by being converted into malt, generally increases two or three per cent. in bulk; and loses, at an average, about 20 per cent. in weight, of which 12 are ascribed to kiln-drying, and consist of water, which the barley would have lost had it been exposed to the same temperature: so that the real loss does not exceed 8 per cent. The roots appear, from the process, to be formed chiefly from the mucilaginous and glutinous parts of the kernel. The starch is not employed in their formation, but undergoes a change, intended, no doubt, to fit it for the future nourishment of the plumule. It acquires a sweetish taste, and the property of forming a transparent solution with hot water. In short, it approaches somewhat to the nature of sugar, and is probably the same with the sugar into which starch is converted by boiling it with diluted sulphuric acid.

The following are the results of Dr. Thomson's analysis of barley and the pale malt made from it:—

	Barley.	Malt.
Gluten	3	1
Sugar	4	16
Gum	5	14
Starch	88	69
	100	100

In brewing ale, porter, and table-beer, three different kinds of malt are employed, which are known as pale or amber malt, brown or blown malt, and roasted or black malt, sometimes called patent malt. The pale or amber malt yields the saccharine or fermentable extract; the brown malt is not fermentable, but is employed to impart flavour; and the roasted malt is employed, instead of burnt sugar, merely to give colouring matter to porter. In the brown and roasted malts the sugar appears to be entirely converted into gum and colouring and extractive matters; and hence they are incapable of undergoing fermentation. The brown malt is subjected to a higher temperature in drying than the pale malt, and by a still further exposure to heat in revolving cylinders or roasters it is converted into black or patent malt.

Most of the changes which have occurred in the malt trade have been due to the peculiar manner in which the product is subjected to duty. Mr. Tyzard introduced a new arrangement of malting apparatus in 1852; and Mr. Plomley, in 1858, devised a mode of making the heat act upon the surface of the malt as well as upon the bottom, in drying; but the foregoing details will suffice to show the general principle on which the operation is conducted. The excise duty has had the effect both of limiting the quantity made, and of checking any improvements in the making. The malt-duty began in England in 1697, in Scotland in 1713, and in Ireland in 1783. In the hundred years from 1716 to 1816 there was scarcely any increase in the quantity of malt made in England; the measure never departing far from 24 million bushels in a year. This stationary condition, at a time when population was steadily increasing, was attributed partly to an increase in the taste for tea and coffee, but chiefly to the effect of duty and restriction. This duty rose gradually from 6d. in 1702, to 4s. 6d. in 1804; it is now a fraction under 2s. 9d. Since 1830, the quantity paying duty has varied from about 30 to 40 million bushels. In 1859 it was 40,406,447, besides 546,743 bushels exempted from duty on various grounds. The price has varied from 2s. 6d. to 10s. 6d. per bushel, during a century and a half, the average being about 4s. 6d. The excise regulations were so very stringent in past years, that the maltsters scarcely knew in what manner to conduct their business. An act, passed to regulate the trade in 1827, contained no fewer than 83 clauses, many of which were difficult of interpretation; more than 100 penalties under it were enforced in three years, amounting to a sum of 13,500*l*. This was replaced by a better statute in 1830, with numerous but intelligible clauses relating to the gauging of cisterns, the wetting of the malt,

emptying of the cisterns, the gauging of the malt when in the kiln, &c. Another act was passed in 1847, still further to facilitate the operations of the maltster without lessening the duty. The Commissioners of Inland Revenue, in a report drawn up in 1857, stated that they were much puzzled by attempts at fraud made by some of the less scrupulous maltsters. One fraud consisted in compressing the grain in the couch, so as to lessen the measure by which the duty was charged. Another fraud was that of mixing raw grain with malt, roasting the two together, and selling the mixture to the brewers as malt. This last trick has been counteracted by an order, according to which grain is to be considered as still unmalted unless the plumule extends half the length of the grain; and by compelling brewers to crush their malt in a way which would not be applicable to unmalted grain.

MALTA, KNIGHTS OF. [HOSPITALERS.]

MALVA SYLVESTRIS (Wild Mallow), an indigenous, perennial, herbaceous plant, of very frequent occurrence, possessed in every part of mucilaginous properties, and which may be employed for the same ends as other demulcent herbs. The flowers only are officinal in Britain: when fresh, they are violet-coloured, but by drying become blue, and also lose a large quantity of their watery constituents, for 100 parts of recent flowers dry into 11. They have no odour, but a mucilaginous herbaceous taste. They yield their colouring principle both to water and alcohol. The alcoholic tincture furnishes one of the most delicate of re-agents for testing the presence of acids or alkalies.

MAMELUKES, or MEMLOOKS, a name derived from an Arabic word signifying slaves, was that of a military body which for a long time ruled Egypt. The Memlooks were first instituted in the early part of the 13th century by Malek Saleh, grandson of Safadeen, which Safadeen was the brother of the famous Salah Edeen, the Koord, the founder of the Eyoob dynasty of the sultans of Egypt, which succeeded the Fatemides. Malek Saleh purchased many thousands of slaves, with which the markets of Asia were then glutted in consequence of the devastating wars of Gengis Khan. He chose chiefly young natives of the Caucasian regions, whom he trained to military exercises, and embodied into a corps of 12,000 men called Memlooks. This corps, by its discipline and distinct organisation, became formidable to its masters. In 1254 the Memlooks revolted and killed Tooran Shah, the last prince of the Eyoobite dynasty, and raised to the throne of Egypt El Moez Turkoman Memlook. El Moez was murdered in 1261 by another Memlook called Baybers, who founded the dynasty of the Baharites, which conquered Syria, took Damascus, and put an end to the domination of the Abbaside caliphs. In 1382 Doulet el Memlook el Borgéeh, a Circassian Memlook, overthrew the Baharite dynasty, and founded the dynasty of the Circassian Memlooks, which, after losing all the conquests of the Baharites in Asia by the hands of the Ottomans, continued to rule Egypt till 1517, when Selim I., sultan of the Ottomans, marched into Egypt, defeated the Memlooks near Heliopolis, took Cairo, and put to death Tomaun Bey, the last of the Circassian dynasty. Selim however maintained the Memlooks as a military aristocracy in Egypt. The Beys of the Memlook, twenty-four in number, continued to be the governors of as many districts, though subject to a pasha, appointed by the Porte, who resided at Cairo. The beys were elected by their own body. [EGYPT, *Modern History of*, in GEOG. DIV.] This aristocracy continued to rule almost independent of the Porte till Bonaparte's invasion, when the bulk of Memlook cavalry was destroyed in several brilliant but useless charges upon the French squares supported by artillery, at the battle of the Pyramids, in July, 1798. The remains of this once splendid body with their beys retreated into Upper Egypt. After the English and the Turks had reconquered Egypt in 1801, the Porte was no longer inclined to allow the Memlooks to retain their former authority, and the Capitan Pasha treacherously murdered several of the beys whom he had invited to a conference. At last, in March, 1811, Mehemet Ali, pasha of Egypt, by a similar contrivance, destroyed 450 of them, among whom were their chiefs, in the citadel of Cairo. [MEHEMET ALI, in BIOG. DIV.] About 1200 escaped into Dongola, but the victorious troops of the pasha pursued them, and they are now extinct as a body. The Memlooks were recruited entirely from Caucasian slaves. The office of bey was not hereditary, but elective among them. Their morals were very depraved: they were rapacious and merciless, and their extinction has been rather an advantage than a loss to humanity.

MANCIPIUM, MANCIPATIO. The right apprehension of these terms is of some importance to those who study Roman authors. The following is the description of *Mancipatio* by Gaius (i. 119, &c.):—"Mancipatio is a kind of imaginary sale, and is a peculiar privilege of Roman citizens. It is effected in the following manner:—There must be present not fewer than five witnesses, Roman citizens, of full age, and also another person, of the same class and condition, to hold the brazen scales, who is called *libripens*. The person who receives in *mancipio*, taking hold of the thing, says, 'I affirm that this man is my property, according to Quirital Law, and I have purchased him with this money (æs) and these brazen scales.' He then strikes the scales with the piece of money, and gives it to him from whom he receives in *mancipio* as the price. In this manner both slaves and free persons are mancipated, as well as animals, which belong to the class of things *mancipii* or *mancipi*, such as oxen, horses, mules, asses; lands also

(prædia), as well in the city as in the country, which are of the class *mancipi*, such as are the Italic lands, are mancipated in the same way. The mancipatio of lands differs from that of other things in this respect only, that persons, whether free or slaves, cannot be mancipated unless they are present, it being necessary that he who receives in *mancipio* should take hold of that which is given him in *mancipio*: whence in fact comes the term *mancipatio*, signifying that the thing is taken (capitur) by the hand (manu); but it is the practice to mancipate lands which are at a distance."

In this passage Gaius describes generally what "mancipatio" is, and, by implication, what things admit of "mancipatio," or, in other words, what things are "mancipi." He was led to these remarks by that part of the subject-matter of his text which treats of the rights of persons, or *status*; and he prefaces his description of "mancipatio" by stating that all children who are in the power of their parents, and the wife who is in that peculiar relation to her husband when she was said in *manu viri esse* [MARRIAGE], are things *mancipi*, and may be mancipated in the same way as slaves. [EMANCIPATION.]

All things, as objects of ownership, were either "res *mancipi*" or "res *nec mancipi*:" and there is, observes Gaius (ii. 18, &c.), "a great difference between things '*mancipi*' and things '*nec mancipi*.' The latter can be alienated by bare tradition or delivery, if they are things corporeal, and therefore susceptible of delivery. Thus the property in a garment, gold, or silver, may be transferred by bare tradition. Lands in the provinces may be transferred in the same way." Thus, "mancipatio" was the proper term for expressing the sale or transfer of things "mancipi;" and "traditio" for expressing the transfer of things "nec mancipi." (Ulpian, *Frag.*, tit. 19.)

It appears then that the ownership of property generally which belonged to that class of things called "res *mancipi*" could only be transferred by the formalities already described: but that the ownership of things which were "res *nec mancipi*," and among them, lands in the provinces, could be transferred without the formalities required in the case of "res *mancipi*." The foundation of the distinction as to lands appears to be this. The real ownership (*dominium*) of provincial lands was either in the Roman people, in which case the lands were called *Stipendiaria*; or in the reigning Cæsar, in which case they were called *Tributaria*. There was therefore no ownership, properly so called, of lands in the provinces by individuals; at least no ownership in the sense in which lands in Italy were held. Lands in Italy held by individuals in full or Quiritarian ownership could be the subjects of usucapion, in *jure cessio*, *mancipatio*, and *vindicatio*; lands in the provinces could not, unless they acquired the *Jus Italicum*. Originally all the conquered lands even in Italy were *Ager Publicus*, the property of the state, and so long as they remained in that condition, nothing beyond the use (*usus fructus*) and occupation of them [POSSESSION] could be in private individuals. Much of the *Ager Publicus* in course of time was assigned to citizens in full ownership, and accordingly it would become "mancipi" and subject to the same rule as to alienation as other lands held in Quiritarian ownership.

Mancipatio could only take place between Roman citizens and Latini Colonarii and Latini Juniani, and those Peregrini who enjoyed the *Commercium*, or privilege of buying and selling. As the effect of Mancipatio was to transfer Quiritarian ownership with its accessory rights of usucapion, in *jure cessio*, *mancipatio*, and *vindicatio*, the reason of the rule is obvious. The form of mancipatio was in some respects a disadvantage, inasmuch as without observing the formalities required by the law, the legal property in a thing "mancipi" could not pass. The mancipatio was that form of transfer of which we find similar examples in the early history of most countries, and implied originally an actual seisin of the thing transferred. No writing being required, it was necessary that there should be some evidence of the transfer, and such evidence was secured by the mode of transfer which the law required. So far as relates to land, mancipatio in its origin may be presumed to have been equivalent to the feoffment with livery of seisin. [FEOFFMENT.]

There was another mode of alienating things "mancipi," by the form called in *jure cessio*, which, according to Ulpian, was applicable also to things "nec mancipi." The *in jure cessio* was a fictitious action before a competent magistrate at Rome, or a praetor, or before a praeses in a province. The purchaser claimed the thing as his, and the seller either acknowledged his claim or made no defence, upon which the magistrate gave judgment for the purchaser. This form was in effect and was called "legis actio." (Gaius, ii. 24.) Its great resemblance to the fictitious suit formerly in use in our own system, called a Fine, might lead to the conjecture that the notion of a Fine was taken by the early practitioners in our courts from the Roman Law; and that this hypothesis is exceedingly probable will be the more apparent, the further any person examines into the connection between the early English and the Roman Law. The *in jure cessio* has apparently a closer resemblance to a Fine than the *transactio* of the Roman Law, to which some writers would refer as the origin of the Fine. (Spence's 'Court of Chancery,' vol. i., p. 142; citing Glanville, viii., c. 1, 2, 3.)

Mancipatio, as Gaius observes (ii. 26), was more in use than the *in jure cessio*, inasmuch as it was easier to transact the business with the assistance of a few friends than to go before a praetor, or a praeses.

Easements (*jura prædiorum*, otherwise called *servitutes*) could be

transferred in the case of lands in the city only by the *cessio in jure*; but in the case of lands in the country, also by *mancipatio*. But this observation applies only to Italic lands; in the provinces, rights of this kind, such as right of road, of conveying water, &c., were matter of contract.

Some difficulty has arisen from the use of the word *nexum* or *nexus*, in connection with *mancipium*. "Nexum" properly signifies that which is bound or obligated, and hence it may signify the engagement or contract. Thus in the laws of the Twelve Tables, in the words, "*quum nexum faciet mancipiumque*," "*nexum*" may signify the contract. Cicero (*Topica*, 5) defines "*Abalienatio*" to be "*ejus rei quæ mancipi est, aut traditio alteri nexu, aut in jure cessio, inter quos ea jure civili fieri possunt*;" from which it follows that there are only two ways of transferring the ownership of things "*mancipi*," and as the *in jure cessio* is here mentioned as one, the *nexus* must represent the other, that is, the *mancipatio*. The "*nexus*" then in this case must be equivalent to the "*mancipatio*," or, as a more general term, must contain the *mancipatio*; for the *mancipatio* does not contain the *nexum*. This would be consistent with Varro (*De Ling. Lat.*, lib. 7,) quoting Mamilius, who says that everything is "*nexum*" which is transacted by the piece of money and scales (*per æs et libram*), which includes *mancipium*: but he adds that M. Scævola considered "*nexum*" to be everything transacted *per æs et libram*, so as to be thereby bound, except things which were transferred by *mancipatio*. Thus, the definition of Scævola would exclude "*mancipatio*" from the "*nexum*," but would include a testamentary disposition, inasmuch as that also was made *per æs et libram* (Gaius, ii., 103), and it would also include that form of marriage called *coemptio*. But if Scævola is right, and this can hardly be doubted, Cicero is wrong in the use of "*nexum*," in the passage quoted. In the "*Orator*" (i. 39) he mentions both "*nexa*" and "*mancipia*" in his enumeration of the various subjects brought before the Centumviri. Assuming Scævola's definition to be correct, Cicero may have properly distinguished "*nexum*" from "*mancipium*" in the passage in the "*Orator*;" and have used *nexu* with some inaccuracy in the passage from the "*Topica*."

Brissonius adopting Gronovius's explanation, maintains that the difference between the *nexus* and the *mancipatio* was not in the form or mode of transfer but in the effect; for whereas no transfer of the dominium or full ownership was necessary when the *nexus* was adopted, the *mancipatio* always conferred a Quiritarian dominium. ('Brisson sub voce *Nexus*.')

MANDAMUS is a writ by which the court of queen's bench, in the name of the reigning sovereign, commands the party to whom it is addressed to do some act in the performance of which the prosecutor, or person who applies for or sues out the writ, has a legal interest; that is, not merely such an interest as would be recognised in a court of equity or in a court of ecclesiastical jurisdiction, but an interest cognisable in a court of common law; the right must also be one for the enforcing of which the prosecutor has no other specific legal remedy. Thus, a copyholder can transfer or alien his customary tenement or estate [COPYHOLD] in no other manner than by surrendering it into the hands of the lord of the manor to the use of the purchaser or surrenderee. The courts of common law formerly took no notice of the right of the surrenderee to call upon the lord for a grant or admittance, and the court of queen's bench therefore left the party to seek his remedy in a court of equity, and would not interfere by granting a mandamus. But the obligation on the part of the lord to admit the surrenderee is not merely an equitable liability, because this mode of transferring property of this nature is founded upon ancient custom, and rights dependent upon custom are matters of common-law cognisance. Of late years the court of queen's bench appears to have taken this view of the subject, and has awarded writs of mandamus in all cases where the lord has refused to admit the party to whose use a surrender of the copyhold has been made. Again, the duty of parishioners to assemble in vestry for parochial objects, whether those objects be of a temporal or spiritual nature, is a common-law duty, and a mandamus will be granted to compel the parishioners to meet. But when they are met, the power of the court to interfere further by mandamus depends upon the nature of the act which the parishioners have to do. If the provisions of a statute are to be carried into execution, the act to be done, whatever its nature, is considered a temporal matter, because the construction of statutes belongs pre-eminently to the courts of common law. But if the object for which the vestry are assembled be one purely of ecclesiastical cognisance, as the setting up of bells, the purchase of books or vestments necessary for divine service, or the making provision for the repairs of the fabric of the church (delinquencies in which matters are punishable by interdict [INTERDICT] and ecclesiastical censures), the court of queen's bench, being without judicial knowledge on such subjects, has no jurisdiction. It is probable indeed that ecclesiastical censures would formerly have been pronounced with less severity against the original delinquents than against those who should have attempted to bring such cases before a lay tribunal. Again, the court can by mandamus compel the visitor of an eleemosynary foundation to hear an appeal, but it has no further authority than "to put the visitorial power in motion." It cannot compel him to do any specific act as visitor.

The term "*mandamus*" (we command) is found in a great variety of writs, and those usually distinguished by this name by the old law

writers are totally different from the modern writ of mandamus, which appears to be nothing more than the ancient "*writ of restitution*" enlarged to embrace a great variety of objects, that writ being adapted merely to the purpose of restoring a party to an office from which he has been unjustly removed.

The writ of mandamus is now granted not only to restore a man to an office from which he has been wrongfully removed, but also to admit to an office to which the party has been duly elected or appointed. It lies for a mayor, recorder, alderman, town-councillor, common-councilman, Burgess, and town-clerk,—for a prebendary, master of a free-school, parish-clerk, sexton, and scavenger,—to hold a court-baron, court-leet, or a borough court of record,—to justices, to do an act within the scope of their authority, and which will not subject them to an action—to restore a graduate in a university to degrees from which he has been suspended,—to a corporation, to pay poor-rates where they have not sufficient distrainable property,—to parish officers, to receive a deserted infant,—to permit inspection of documents of a public nature in which the party is interested,—to appoint overseers of the poor,—to swear in churchwardens,—to proceed to the election of a corporate officer,—to grant probate or letters of administration,—to affix the common seal to an answer agreed to by the majority of the members of a corporation aggregate,—and to allow a poor-rate, in which case the rule for a mandamus is absolute in the first instance.

The mandamus is said to be a prerogative writ; by which is meant, —either that the power to award is not delegated by the crown to the ordinary judges between party and party, that is, the justices of the common pleas, but is reserved for that court in which the king is supposed to be personally present,—or that it is a writ of grace and favour granted according to discretion, and not a writ of right, that is, not such a writ as the party applying for it has a right to call upon the court to issue under the clause of Magna Charta, by which the king binds himself not to refuse or delay justice or right.

In order to obtain a mandamus the applicant lays before the court the affidavit of himself or others presenting the facts upon which his right and interest in the thing to be done, and his claim or title to the remedy, are founded. Upon this application the court, if it see a probable cause for interference, grants a rule calling upon the party against whom the writ is prayed, to show cause why such writ should not be awarded, or the court may grant a rule absolute in the first instance (17 & 18 Vict., c. 125, s. 76).

In the case of a mandamus to elect a corporate officer, if the applicant gives ten days notice of the application, with a statement of the grounds, and a copy of the affidavits, cause may be shown in the first instance. (6 & 7 Vict., c. 89, s. 5.) In other cases at the appointed time the party called upon either does not appear, in which case the rule is made absolute, and the mandamus is awarded as prayed, or he appears and resists the rule, either by insisting upon the insufficiency of the facts disclosed by the affidavits upon which the rule was obtained, or by producing other affidavits which give a different aspect to the transaction. If the resistance be effectual the rule is discharged; if not, the mandamus is awarded.

The writ, in the first instance, issues in an alternative form, requiring the party to do the act, or to show why he has not done it. The party may therefore make a return to the writ, saying that he has not done the act required for such and such reasons. Where the reasons returned are insufficient in law, the court quashes the return, and awards a peremptory mandamus requiring the party absolutely, and without allowing him any alternative, to do the act. Where the answer is apparently sufficient, the mandamus is at an end; and if the statements are untrue, the remedy is by action on the case for a false return, though in order to avoid expense and delay the party is allowed in some cases, by the statute 9 Anne, c. 20, and now in all cases, by 1 Will. IV., c. 21, to engraft an action upon the mandamus itself by traversing the return, namely, by putting in a plea contradicting the allegations contained in such return (*Comyns's Digest*; *Selwyn's Nisi Prius*); and the prosecutor may demur to the return, and a writ of error lies upon the judgment (6 & 7 Vict., c. 67).

Besides this prerogative writ of mandamus, the plaintiff in any action in the superior courts, except replevin and ejectment, may now indorse upon the writ and copy to be served, notice that he intends to claim a writ of mandamus, and the plaintiff may thereupon claim in the declaration, either together with any other demand which may be enforced in such action, or separately, a writ of mandamus, commanding the defendant to fulfil any duty in the fulfilment of which the plaintiff is personally interested. (Common Law Procedure Act, 1854; 17 & 18 Vict., c. 125, s. 68.) The Court of Queen's Bench has held that this provision is confined to those cases where a writ of mandamus might have been applied for. (*Benson v. Paull*, 2 Jur., N. S. 425.)

Besides these provisions facilitating the writ of mandamus, justices of the peace may now be called upon by a rule in the ordinary way, to perform their duties (11 & 12 Vict., c. 44, s. 5), and so may judges or officers of the County Court (19 & 20 Vict., c. 108, s. 43).

MANDARINS is the general name of the officers of state in China. They are chosen from the men of letters or scholars from every part of the empire, who, having obtained their degrees and passed their examination, have their names inscribed in a register kept by a court or board established for this purpose. When an office in the adminis-

tration is vacant, the court presents to the emperor a list of those who stand foremost on the register, from among whom the monarch appoints one to fill up the vacancy. Sometimes when there are several candidates equally qualified they draw lots for the vacant office. In Duhalde's time there were 13,600 mandarins all over the empire, independent of the military mandarins, or superior officers of the army. The civil mandarins are divided into nine classes, the highest of which, called Choong-t'hang or Kō-laon, are ministers of state, counsellors of the emperor, or presidents of the supreme courts. The governors of provinces rank in the second class. The secretaries of the emperor belong to the third class; the governors of cities to the fourth class, and so on. Each order has its distinctive mark of dignity. All is gradation and strict subordination among them.

MANDATE, as one of the contracts of the Roman law, was constituted where one by special agreement, or by tacit assent, had undertaken to perform some act gratuitously for another. The obligations incumbent on the mandatary, and enforced against him by law, arose, not from his receiving a consideration for what he had undertaken to do, but from his leading the mandant to believe that he would perform it, and thus causing damage if he should neglect it. It is distinguished from *negotiorum gestio*, where the person performing the service undertakes it without authority from the person for whose behoof it is undertaken; and from *locatio-conductio*, where the service is remunerated. The characteristics of *mandatum* are briefly stated in Heineccius, 'Ad. Inst., tit. 27, and by Gaius, iii. 155, &c. In England, mandate in this simple sense is a department of the law of bailment. [BAILMENT.] In Scotland there is a wide departure from the old Roman meaning of the word, almost every instance where one person acts for another being referred to the contract of mandate; thus the commercial agent buying and selling, and the solicitor conducting a litigation, are said to be "mandatories." The case in which, by the practice of the law of Scotland, the word mandate in its old sense is best exemplified, is in trusts, which, instead of being subject to the complex legal peculiarities which characterise the system in England, are merely treated as simple mandates.

MANDELIC ACID. Synonymous with *Formobenzöilic acid*. [FORMYL, *Formobenzöilic Acid*.]

MANDOLINE, a musical instrument of the lute kind, but smaller, having four strings, which are tuned as those of the violin. The mandoline is still met with occasionally in Italy, but has fallen into disuse in most other parts of Europe.

MANDORE, a musical instrument of four strings, of the lute kind, no longer in use under such name.

MANES, the name given by the Romans to souls separated from the body. According to Apuleius ('De Deo Socrat.'), they were originally called *lemures*, and were divided into two kinds; *lares* and *larvæ*; the former being the souls of such persons as had lived virtuous lives, and the latter of such as had been wicked, but afterwards the name of manes was applied to both. [LARES.] The etymology of manes is uncertain; it is generally derived, by ancient grammarians, from an old word, *manus*, signifying "good," probably in the same sense as the Furies were called Eumenides by the Greeks. Some considered the manes as the good and bad genii which accompanied a man through his life; but this notion appears to have been introduced by the later Platonists.

The stones in the Roman burial-places and their funeral urns were generally inscribed with the letters D. M. S.—that is, *Dis Manibus Sacrum*, "Sacred to the Manes Gods." There are many specimens of such funeral inscriptions in the British Museum. It was the duty of the Pontifex Maximus to see that the Manes were propitiated by proper ceremonies (Liv., i. 20); and with this object it was usual to pour libations of wine on the funeral piles, and also sometimes to slaughter animals, especially such as the deceased had been fond of. (Plin., 'Ep.,' iv. 2.) The 19th of February was dedicated as an annual festival to the Manes, under the title of Parentalia, or Feralia, when it was the special duty of children and heirs to offer sacrifices to the Manes of their ancestors. (Ovid, 'Fast.,' ii. 535; Virgil, 'Æn.,' ix. 258; Gaius, ii. 4.)

MANETTIA CORDIFOLIA is a Brazilian twining plant, whose roots possess considerable emetic energy. The bark is administered in Brazil in powder, in doses of $\frac{1}{2}$ to $1\frac{1}{2}$ drachms, and is considered a most valuable remedy in dropsy and dysentery. (Lindley's *Flora Medica*, No. 862, p. 432; Maund's *Botanist*, vol. ii., pl. 87.)

MANGANATES. [MANGANESE; *Manganic Acid*.]

MANGANESE (Mn). This metal was not isolated till about the middle of the 18th century, the natural compounds containing it having been up to that time supposed to be ores of iron. It is a constituent of many minerals and, as black oxide, occurs frequently in abundance. The composition of its ores, and the localities whence they are derived, will be found described under MANGANESE, in NAT. HIST. DIV.

Metallic manganese may be obtained, though with difficulty, by igniting carbonate of manganese made up into a paste with oil and sugar. For this purpose, a crucible should be lined with charcoal, the cover luted on, and the whole exposed to the heat of a smith's forge for a couple of hours. A button of metal is thus procured which may be purified by re-igniting in a crucible with a little more of the carbonate.

Manganese is a grayish white metal of inferior lustre, is hard enough to scratch steel, is very brittle, easily split, feebly magnetic, has a granular texture, and a specific gravity of 8.013. When pure, it speedily absorbs oxygen from the air, and is therefore most conveniently kept below the surface of naphtha. It appears to exist in two allotropic modifications, and combines with carbon and with silicon when fused in contact with those substances. In the finely divided state it slowly decomposes cold water; hot water being rapidly attacked by it, with liberation of hydrogen. Most acids act upon it energetically.

The equivalent of manganese is 27.57. Its specific gravity, 8.013.

Manganese and oxygen unite in seven different proportions; two of the resulting compounds are, however, usually considered to be mixtures of the other oxides. They are:—

1. Protoxide	MnO
2. Sesquioxide	Mn ₂ O ₃
3. Binoxide	MnO ₂
4. Red oxide (Hansmannite)	Mn ₃ O ₄
5. Varricite	Mn ₄ O ₇
6. Manganic acid	MnO ₃
7. Permanganic acid	Mn ₂ O ₇

1. *Protoxide of manganese* (MnO). *Manganous oxide*. Obtained on heating carbonate of manganese in a current of hydrogen. It is a green coloured powder, and if prepared at a dull red heat, has such affinity for oxygen as to be spontaneously inflammable. It is a powerful base, and forms stable salts with the acids.

Hydrated protoxide is a white precipitate produced on adding an alkali to an aqueous solution of a manganous salt. In contact with air it rapidly absorbs oxygen and becomes brown.

2. *Sesquioxide of manganese* (Mn₂O₃) is formed when the protoxide is exposed to the air. It is a feeble base, isomorphous with alumina and sesquioxide of iron.

It occurs native as *braunite*. Its solution in dilute sulphuric acid is red, and on the addition of an alkaline sulphate, octohedral crystals are deposited, resembling alum, but having Mn₂O₃ in the place of Al₂O₃. The potash salt contains Mn₂O₃, 3SO₃ + KO, SO₃ + 24Aq.

Hydrated sesquioxide is produced by exposure of the hydrated protoxide to the air. It also occurs native. [MANGANESE, *Manganite*, in NAT. HIST. DIV.]

3. *Binoxide of manganese* (MnO₂). *Peroxide of manganese*. This oxide occurs largely in nature, and is called *pyrolusite* by mineralogists, see NAT. HIST. DIV. In commerce, it is generally simply termed *manganese*, and is largely used in the manufacture of chlorine compounds, also to give a black colour to earthenware, and in GLASS MANUFACTURE (vol. iv., col. 391).

When heated, binoxide of manganese yields up one-third of its oxygen; boiled with sulphuric acid it is converted into a salt of the protoxide, oxygen here also being eliminated.

The assay of *binoxide of manganese* is an important operation connected with the manufacture of bleaching-powder. It depends upon the conversion of oxalic acid into carbonic acid, by the action of the oxygen that is evolved when binoxide of manganese is heated with sulphuric acid. The apparatus in which it is performed is weighed before and after the evolution of the carbonic acid, and the loss sustained, that is the weight of the carbonic acid, exactly indicates the weight of peroxide of manganese in the sample.

4. *Red oxide of manganese* (Mn₃O₄, or MnO + Mn₂O₃, or 2MnO + MnO₂) occurs native. [MANGANESE, *Hansmannite*, in NAT. HIST. DIV.]

5. *Varricite* (Mn₄O₇, or Mn₂O₃ + 2MnO₂). See also MANGANESE, in NAT. HIST. DIV.

6. *Manganic acid* (MnO₃). Equal parts of caustic potash and binoxide of manganese are fused together, the mass being frequently stirred to promote absorption of oxygen. The resulting green mass is *manganate of potash*.

7. *Permanganic acid* (Mn₂O₇). *Hypermanganic acid*. When a strong solution of manganate of potash is poured into warm water, it immediately commences to pass through several successive changes of colour, and hence has received the name of *mineral chameleon*. The final colour is a purple, and is owing to *permanganate of potash*. The latter salt is however more quickly prepared by fusing binoxide of manganese with caustic alkali and a nitrate or chlorate.

The *permanganates* are far more stable salts than the *manganates*, and are mostly crystallisable. The potash salt occurs in beautiful prismatic crystals. Permanganic acid may be isolated, but not manganic acid.

The manganates and permanganates have of late years come into use as oxidising agents, especially for purposes of disinfection, as they readily yield up their oxygen to organic matter.

Manganese and sulphur form one compound, namely,—

Sulphide of manganese (MnS). *Manganous sulphide*. It occurs native as *manganese blende*, and is precipitated of a flesh colour when an alkaline sulphide is added to a solution of a manganous salt. It is soluble in acetic acid, a property taken advantage of in separating manganese from nickel and cobalt.

The *iodide*, *bromide*, and *fluoride* of manganese are unimportant salts.

Manganese and chlorine form—

Protochloride	MnCl
Sesquichloride	Mn ₂ Cl ₃
? Perchloride	Mn ₂ Cl ₇

Protochloride of manganese (MnCl) is the only important chloride. It is largely produced in the preparation of CHLORINE. By evaporation its solution yields pink crystals containing four equivalents of water of crystallisation.

Carbonate of manganese (MnO, CO_2) is a buff-coloured powder precipitated when an alkaline carbonate is added to a manganous salt.

Sulphate of manganese ($\text{MnO}, \text{SO}_3 + 7\text{HO}$, and sometimes $\text{MnO}, \text{SO}_3 + 5\text{HO}$). Formed by treating the binoxide with strong sulphuric acid. It is a rose-coloured soluble salt, isomorphous with sulphate of magnesia. It is largely used in dyeing and calico-printing. It forms double salts with alkaline sulphates.

Nitrate of manganese is a deliquescent salt occurring in acicular crystals.

Silicates of manganese. Several of these occur native. [MANGANESE, in NAT. HIST. DIV.]

Tests for manganese.—The non-precipitation by sulphuretted hydrogen, and the formation of the sulphide and hydrated oxide in the manner already indicated, readily characterise the protosalts of manganese. Manganese is also detected by the production of an amethystine bead when a very small quantity of the substance under examination is heated with borax in the blow-pipe flame.

Estimation of manganese.—Except for the valuation of the binoxide, this is usually effected by precipitating the carbonate and igniting it in an open crucible, whereby the red oxide (Mn_2O_3) is produced, containing 72.7 per cent of metal.

MANGANESE ALUM. [ALUMS.]

MANGANESE, Medical Properties of. During the prevalence of pneumatic medicine, preparations of manganese, particularly the binoxide, on account of the large quantity of oxygen it can yield, were much employed; but since the views of Beddoes and others, who recommended them, have become obsolete, the articles suggested to be used have fallen into oblivion. A rational ground for reviving some of them is to be found in the facts that oxide of manganese exists as a constituent of the bones, and may in some cases be deficient in these structures, and also that carbonate of manganese exists in some of the mineral springs of Carlsbad and Marienbad, and hydrochlorate of manganese exists in the waters of Kreutznach. The presence of these salts in waters much celebrated for their utility in various chronic diseases has suggested their employment in some of the complaints which are frequently benefited by them. But even if their curative properties are insufficient to establish them as valuable medicines, the deleterious effects of some forms of manganese justify a notice of them in this place. The extensive employment of black oxide of manganese in the preparation of bleaching-powder produces in some of the workmen a form of paralysis which should be early noticed, inasmuch as after it is thoroughly established it seems altogether incurable, and the only chance of escape is the complete abandoning of the occupation. It is limited to paralysis of the lower extremities, affecting the motor nerves only, for the sensibility is unimpaired. A staggering gait is the first symptom of its commencement: this is often perceived sooner by others than by the sufferer. No choleric, nor constipation, such as attends the use of lead, is manifested. (See Dr. Couper's paper in 'British Annals of Medicine,' i., p. 41.)

Binoxide of manganese has been used internally in pills, and also as a gargle; externally as an ointment in some obstinate cutaneous affections. It does not appear entitled to much attention. Hydrochlorate, and still more sulphate, of manganese, deserves attention as chologogue cathartics, or promoters of the secretion of bile. The latter salt has a cooling and bitter taste, resembling that of Glauber salts. Dissolved in a considerable quantity of water, and taken in the morning, it produces several liquid stools. Its purgative action may be increased by giving it with infusion of senna or with rhubarb. Alkalies and their carbonates are incompatible with it, as decomposition occurs. Its power of augmenting the secretion of bile renders it a valuable agent along with mercury, or as a substitute for it where mercury cannot be borne. It is useful in gout. Care must be observed in using it, as in doses as large as some writers have recommended, it causes dangerous, if not fatal, consequences.

The sulphated ferro-manganous waters of Crausac, a village in the south-west of France, between Bordeaux and Toulouse, with springs in which this combination exists in two different degrees of strength, present a valuable means of benefiting feeble systems.

The manganate of potassa, known by the name of "mineral chameleon," furnishes a useful caustic and escharotic, especially for foul and fetid ulcers.

Manganic acid and permanganate of potass are very valuable disinfectants. Manganic acid is employed as a means of testing the purity or degrees of impurity of the air. [DISINFECTANTS.]

MANGANIC ACID. [MANGANESE.]

MANGE, an eruptive disease to which dogs, and all the canine race, as wolves, foxes, &c., as also horses, are subject. It usually occurs as the result of dirt and confinement, bad or deficient food, or some other circumstances producing a generally unhealthy condition. There are several forms of mange, but the red mange and the common scabby kind are the most frequent. It has many analogies to the itch in man [ITCH]; and the fluid discharged from the eruption of the mange in horses and dogs has sometimes been known to produce the itch in the human skin. Both appear to depend in general on the presence of a

ARTS AND SCI. DIV. VOL. V.

minute species of *Acarus* which burrows beneath the skin, and thus excites the irritation and itching by which these diseases are peculiarly characterised. The cure is to be effected chiefly by the use of preparations of sulphur, outwardly and inwardly; but the mange in dogs is usually difficult of cure.

MANGLE. [CALENDERING.]

MANGOLD WURZEL. For many years this plant has been increasing in agricultural importance. When well grown it is a much larger root than the Swedish or common turnip, and as it is cultivated more easily and with greater certainty, at the same time that it is, during most of the season, a better food, no wonder that its cultivation is increasing. It is more easy to get 30 tons of mangolds per acre than 20 tons of swedes; indeed, the latter crop is becoming more hazardous and unsatisfactory year by year, while every year mangolds are increasing in the estimation in which they are held. They are not liable to the attack of fly or caterpillar, and though a grub occasionally penetrates the leaf and eats out the substance of it, and though it is at midsummer sometimes attacked by a sort of canker, which appears to scorch the plant and check its further growth, yet it is much less liable to injury or disease than any other of our root crops; and sown as it is earlier in spring time than the turnip, it is sure of sufficient moisture during its early growth. In summer time it stands hot weather better than the turnip, and in the autumn it grows more rapidly to maturity. It needs to be harvested, pitted, or otherwise protected, before frost comes on, as it is not so hardy as the turnip, and this is the only point in which it is inferior. The cultivation of mangold wurzel very much resembles that of the turnip crop. It is usual to give it a heavier dressing of dung than the turnip receives, and this on heavy soils, which it rather affects, may well be put on in the autumn, thus leaving for spring time less occasion for anything beyond mere surface harrowing and stirring. The best way to prepare the land is, after a sufficient cleaning and stirring, to lay it up in ribs or drills at least 30 inches wide, to cart on 10 to 20 tons of farm-yard dung, per acre and cover it up before winter, by splitting the drills with the double mould-board plough. If this is not done till spring time, then before the dung is covered, it is well to sow broadcast whatever artificial manure is added; as, for instance, 3 cwt. of guano per acre, or 4 or 5 cwt. of a superphosphate, or blood manure. The splitting of the drills covers up this artificial dressing, at the same time that it gathers it somewhat together in the drill on which the seed is to be drilled or dibbled. Seven pounds of the seeds are needed per acre, and they may be soaked for a day or two in water before sowing, if it be desired to have an early braird. If drilled a row comes up along the top of each drill, and is afterwards singled out to intervals of 15 or 18 inches. If dibbled, three or four of the seed capsules are thrust into the soil with the half-closed hand, which holds them, so as not to place them deeply, and soil enough is laid upon them by a sliding half-pressure of the foot. The mangold seed is easily buried; half an inch of soil is more than covering enough. The seed thus comes up in bunches, the intervals between the rows are horse-hoed, and the intervals between the bunches are hand-hoed, and the bunches themselves are singled out by hand as soon as they are 2 or 3 inches high. Repeated horse-hoeings, and another hand-hoeing constitute the summer cultivation; and after a moist season, on good land well manured, a crop of 40 tons per acre is not an unusual produce. At the intervals of 30 inches and 18 inches respectively between the rows and the plants, about 11,000 plants may be expected per acre, or about 5 tons for every single pound the plants may average in weight; and 8 lbs. a piece is not an impossible average weight to attain.

Among the sorts are the red and yellow, and white, as to colour, and the globe, long, and bulged, as to shape.

The long red Elvetham which has a bulged shape is one of the best; the globe mangolds are probably the best for retaining their juice and freshness till a late period in the following year; for this is one principal advantage of this root, that it retains its value all through the summer, and is thus a most valuable food to keep for those awkward periods in a drouthy season, which sometimes intervene between the successive forage crops on which the farmer depends for the continuous feeding of his stock. The mangold has hitherto been regarded as rather physic than food if taken early in the autumn; and there is an impression against it too as to its unfitness for breeding stock; there is also a feeling that it exhausts the land more than turnips for the ensuing grain crop.

On the first of these points we have now ample experience of its perfect safety however early it be given as food, the only thing needed as precaution being that it should be grated rather than cut in pieces, and mixed with chaff of straw and hay, rather than given whole, along with unchaffed fodder. The root-graters, which of late years have come into general use, are admirably adapted to this treatment of the mangold root, and any proportion between the succulent and the dry food may be thus adopted quite apart from any power of selection on the part of the animal thus fed, which may thus be provided with food just in the proportion needed to keep their faeces of the right consistence. This root, when thus gradually given to cattle, or sheep, or swine, may also be safely given to them when in breeding condition. It is a sudden change of food which is injurious to animals in that state, especially if it be from comparatively dry to succulent food. Mangolds are very succulent, but if animals are gradually accustomed

G G

to them, and at the same time drier food be mixed with them whenever the necessity is seen, no harm has been done by their free use for either sheep, pigs, or cows.

The impression that mangolds are an exhaustor of the soil, has a real foundation in the fact that they generally produce twice as great a crop as swedes do; but probably the chief cause for the belief exists in the fact that swedes are generally consumed on the land by sheep, whereas mangolds, owing to their being less able (in fact unable) to withstand the frost, are more generally removed from the land and consumed in yards.

In order to protect this crop from the frost it must be lifted early in October, and carried to heaps either in sheds, or in pits on the ground and covered up with straw and earth. It is well to let them remain for a fortnight lightly covered with straw before covering them up with earth, as time is thus given for ventilation, and they dry a little, and are less liable to ferment and rot when in the closed heap. They may be gradually brought into consumption from early autumn, and given to all sorts of stock with perfect safety; but it is in late spring, and even through the summer, that their greatest value as feeding stuff is seen. When swedes and turnips get tough and pithy, they are still crisp and juicy, and increase in sweetness as they increase in age.

For small dairies the mangold is especially valuable, as during autumn a few of the lower leaves of the plant, still good as food, may be removed from it for that purpose and given to the cows. The mangold produces a poor milk, and a white butter, when given as the only food. This butter has a slightly bitter taste, but it has no such disagreeable taste as when derived from the consumption of turnips or cabbages.

MANGOSTIN ($C_{10}H_{22}O_{10}$?). A peculiar crystalline principle contained in the fruit of the *Garcinia mangostana*.

MANIA. [INSANITY: LUNACY.]

MANICHÆANS, [MANI, in BIOG. DIV.]

MANICHORD, a keyed musical instrument, of the spinnet kind, similar in all respects to the clavichord. [CLAVICHORD.]

MANIPULATION, CHEMICAL, the mechanical operations performed in the chemist's laboratory. For several such operations connected with chemical analysis, see **CHEMICAL ANALYSIS**; and for further details in that and other descriptions of chemical manipulation, see Faraday's 'Chemical Manipulations,' and 'Handbook of Chemical Manipulation' by Greville Williams, 1857.

MANNA, the concrete juice of the *Ornus Europæa*, and *Ornus Rotundifolia*, species of flowering ash which are natives of the South of Europe, growing abundantly in Sicily, Calabria, Apulia, &c. The juice exudes spontaneously in warm dry weather, and concretes upon the bark of the tree. It occasionally flows from the leaves, forming tears, now rarely met with in commerce. The flow is thought to be the result of the puncture of the *Cicada Orni*, Linn.; *Tettigonia Orni*, Fabric. It has a slight peculiar odour, and a sweetish taste, mixed with a slight degree of bitterness, and altogether leaves a disagreeable impression. Its texture is generally granular; but the finer pieces when broken are often hollow, and when examined by the microscope exhibit spicular crystals. Manna is perfectly soluble both in water and in alcohol; the crystals deposited by cooling a hot spirituous solution constitute a peculiar variety of sugar, which has been called *mannite*; it differs however from common sugar in not being fermentable. According to Bucholz, 100 parts of flake manna contain about 60 of mannite, mixed with uncrystallisable sugar, purgative principle, gum, &c.

Mannite is composed of—

	Prout.	Liebig.
Hydrogen	6.8	7.62
Carbon	38.7	40.02
Oxygen	54.5	52.35
	100.	99.99

Manna is employed as a gentle laxative, for children or persons of weak habits. It is however seldom exhibited alone, but as an adjunct to other more active medicines, as senna, rhubarb, &c. [FRAXINUS, MANNA, in NAT. HIST. DIV.]

MANNITE ($C_{12}H_{22}O_{12}$). *Mushroom Sugar*, *Grenadin*, *Fraxinin*. The juices of many plants contain a peculiar saccharine matter called mannite, which forms the principal constituent of the drug *manna*—the inspissated juice of the *fraxinus ornus*. Mannite is also found in celery, asparagus, onions, and several kinds of fungi. It is formed in large quantity in the process for preparing lactic acid, and finally it occurs in some descriptions of cider.

Mannite is most easily obtained in a state of purity by digesting manna in hot alcohol; on cooling the filtered solution, the mannite is deposited in crystals which fuse at 320° , are very soluble in water and possess a sweet taste. Mannite may be distinguished from cane sugar by forming *sulphomannitic acid* ($C_6H_7O_6, 3SO_3$), without any charring when treated with sulphuric acid; from grape sugar it is also distinguished by not becoming brown when heated with solutions of the alkalis.

Mannite is not susceptible of alcoholic fermentation; nitric acid converts it into saccharic and oxalic acids, whilst a mixture of sulphuric

and nitric acids transforms it into *nitromannite* $C_{12}H_5(NO_4)_6O_{14}$. Fused with hydrate of potash it gives a mixture of formiate, acetate, and propionate of potash:

Heated with several of the acids mannite yields bodies resembling ethers, which under the influence of alkalis regenerate the original acid and a body named *mannitane* ($C_{12}H_{12}O_{10}$). The latter in contact with water gradually assimilates two atoms, and becomes reconverted into mannite.

Dulcose or *Dulcin* ($C_{12}H_{14}O_{12}$) and *Phycite* ($C_{12}H_{14}O_{12}$) are saccharine substances isomeric with mannite. *Quercite* ($C_{12}H_{12}O_{10}$) is also closely allied with mannite, and like the latter is converted into a detonating compound, *nitroquercite*, when treated with a mixture of nitric and sulphuric acids.

MANNITANE. [MANNITE.]

MANŒUVRES, or **MILITARY EVOLUTIONS**, are the movements made by any body of troops, either acting by itself or in conjunction with other bodies, for the purpose of arriving at or of retiring from a field of battle, or of placing itself in a position to act offensively or defensively against an enemy.

The circumstances attending the great movements of armies along their lines of communication, and the dispositions of the troops on the field of battle, are developed under the words **STRATEGY** and **TACTICS**. The present article will therefore comprehend merely a description of the manner in which the principal evolutions of a battalion of infantry, a regiment of cavalry, and an entire army, are performed, and will conclude with a short account of the movements of light troops in the field.

Evolution of a Battalion.—When a battalion formed in line has to march in that order towards the front or rear, in order to ensure exactness in the movement, the centre serjeant, who is between the two colours, selects two points to march on under the superintendence of a mounted officer. When the line of direction is determined on, he gives the word "steady;" and on the word "quick march" being given, the battalion moves off, dressing by this serjeant, who moves straight to his front in this direction. To see that the centre serjeant preserves his direction correctly, the serjeant-major and a mounted officer remain halted until the line has advanced 20 or 30 paces; they then follow in rear. In the same way, when retiring, on the battalion facing about, the serjeant-major and a mounted officer pass through the ranks and place themselves behind the centre to superintend the movement. While the battalion is thus moving in line, the two flanked companies may be wheeled backwards, and made to march in files perpendicularly to the line of the battalion, in order to cover it; and on a halt being ordered, they would face towards the enemy.

This order of march can of course only take place where the country is open; when partial obstacles occur, the troops near them necessarily form in file till they have passed them, and afterwards they move up into the line, or the companies may advance by files or fours from the right or left; but when the obstacles are of great extent, and occur frequently, it is evident that the march of the battalion should be in column.

Columns formed for this purpose are designated columns of companies, of subdivisions, and of sections, according as their breadths, or the extent of their front, is equal to that of a whole, a half, or any portion of a company; and they are said to be at open order, at half, or at quarter distance, according as the intervals between the companies or their divisions are equal to the whole, to one-half, or to one-quarter of the breadth of the column. The order is said to be close when the several divisions are at the distance of one pace only from each other in the length of the column. When the company or subdivision whose position is on the right of the line is in front, the left of that company or subdivision is called the pivot, and the right the reverse flank, and *vice versa*; that is, when the right is in front the left is the pivot, when the left is in front the right is the pivot, because, in reforming line, the wheel, except in wheeling backwards, must evidently be on this flank; for if the wheel were made on the other flank, the companies would become inverted.

The wheel from line into column, and the converse, when the battalion is at a halt, must obviously be performed by causing the divisions to describe a quarter of a circle on their respective pivots. But when a battalion in column is on the march, and it is required to change the route, should the divisions be at the full distances from each other,—that is, at intervals equal to the length of a division,—it is necessary that the first division, after having described on its pivot an angle equal to that which the new direction is to make with the former, should march forward as soon as the wheeling pivot of the next division has arrived at the like pivot of the first division; the second division then wheels and marches in like manner, and so on. The same rule may be followed when the divisions are at less than full distance, provided the angle which the intended direction of march makes with the former is sufficiently obtuse to allow the divisions to describe the required angle without interfering with one another, otherwise the wheeling is performed in this way: the leading company wheels round at a short pace, so regulated as to give time for the

remaining companies to circle round the flank on which the wheel is being made. This is done by the rear companies, when at the halt, making a half-face to the right, or on the march a half-turn to the right (supposing the wheel to be to the left), and each man moving round on the circumference of a circle of which the wheeling-point is the centre. The wheelings may be made upon either extremity of a company or subdivision, and they may take place either forward or backward, according to circumstances; occasionally, also, a company is required to perform a wheel upon its centre, in which case one-half wheels backward and the other half forward; but in all cases the pivot-flanks are to remain dressed, or in one line.

When a battalion is formed into a column for the purpose of an attack, it is called a column of manœuvre; and when so formed in order to move along a road or through a defile, a column of route. In either case the column may be in open order, at half or at quarter distance, or in close order; and in the first formation the column, of course, occupies in length an extent of ground equal to that which it occupies in line, minus the length of the first division. Columns at half or at quarter distance, or at close order, have the convenience of moving upon less space than the open column, with equal capacity of forming in any manner that may be required for resisting an attack; and their compact order enables them to avoid the evils attending the loss of distances which may occur with an open column, from the inequalities of the ground.

The battalion in line may be formed into a single or double column: the former upon or in rear of either flank company, and the latter upon the two centre companies or the two centre subdivisions. In either case the column is equally fit for its purpose, and the preference of one to the other must depend upon the ground or upon the point to which the movement is to be directed: the single column, however, can always be diminished to the smallest degree, according to the defile; whereas the double column, if much diminished, may be in danger of becoming disordered by the intermixture of the files. For an attack, the column formed on the centre of a battalion can be more rapidly brought to bear upon the required point than a column formed on one of the wings, seeing that the divisions in line have but half the distance to march through in order to arrive at their places in the column, and a corresponding advantage is enjoyed when the battalion has to deploy from column into line.

It is to be observed that the front of a column should never be unnecessarily contracted, and battalions should be so instructed as to render it indifferent whether the first or second rank is in front, or whether the right or left flank division (of the line) is at the head of the column; but occasions may occur in which the order of battle is to be reversed, and then the divisions must necessarily change their positions by countermarching.

A battalion in column at open order is formed in line to the front by the rear companies wheeling backwards an eighth of a circle on their right or left, according as the right or left is in front, and then moving up in this direction the inward flank comes up to the alignment or flank of the halted company, then wheeling an eighth of a circle to the left or right, brings them up into line—or if the line is to be formed to a flank by merely causing the divisions to wheel upon their respective pivots; but a close column of companies, having its head already in the alignment, is *deployed* by causing the several divisions to move out by files to the right or left parallel to the alignment; each division having got beyond that which was in front of it turns to the left or right, and then marches up to its place in the line. The deployment may take place upon any one of the companies; should it be on one of the rear companies, it has to remain halted till its front is clear, when it moves up at a double—the other companies halting in the same way till their front is clear, and then moving up.

Echelon movements are performed when it is required to advance or retreat obliquely, and when a change is to be made in the position of a line, corresponding to a wheel of the whole about some given point: the movements are made to the front when an enemy's flank is to be turned, and to the rear when it is required to cover the flank of the line itself. Echelon movements are the safest that can be adopted by troops in presence of the enemy, as they have the advantage of preserving a general front during the march. A direct echelon, as it is called, may be formed by the different companies or subdivisions marching from their position in the line towards the front or rear, keeping parallel to that position, and halting successively when arrived at the required distances. The oblique echelon is formed by causing the different companies or subdivisions to make a wheel upon their pivots through any angle less than a right angle, but generally not more than one-eighth of it; the position and parallelism of the divisions being ensured by causing a non-commissioned officer of each division to place himself, as the case may require, before or behind the eighth file from the pivot, then by his taking paces of 30 inches (the regulation pace) on the arc of a circle, of which the pivot is the centre, he may indicate an alignment of any portion of the circle $\frac{1}{16}$, $\frac{1}{8}$, $\frac{3}{16}$, or $\frac{1}{4}$, that may be required, every 2 paces giving $\frac{1}{16}$ of the circle; the division is then to wheel up to the place where he halts.

An important evolution of a battalion is that of placing itself in a square or oblong form, with the men on the four sides facing outwards, so as to be enabled to resist an enemy who may attempt to surround them. This figure is generally formed hollow, or so as to inclose a

space in which are the officers, or in which baggage or treasure may be placed for security; if otherwise, it is evident that great numbers of the men would be useless, since they could not use their fire-arms.

When a battalion in open column forms square on the leading company, the leading company, if moving, halts—the second company closes up to it and halts, the remaining companies, except the two last, wheel outwards by sections successively on coming up to quarter distance from those that precede them, the flank sections halting when they have wheeled the quarter circle, the others closing up to them. The two rear companies closing up and being faced about form the rear of the square.

When a battalion in line is to form a hollow square, the manœuvre may take place upon any given company, generally the left centre company, or upon one formed of the two contiguous subdivisions of two companies, which then for the moment remain at rest; while the other companies break out of the line and march to the rear of the troops who are stationary. The second division in the column marches close in rear of the first, and these two form the front of the square; the remaining companies march by fours, so as to form a column of companies at quarter distance in rear of these, when all, except the two last, wheel by sections outwards, as in forming square from column, and form the sides of the square: the last closes up to the next to it, and these two form the rear of the square. If the square is to resist an attack of cavalry, the two front ranks kneel and slope their firelocks outwards till, at the word of command, they fire a volley: the men in the two standing ranks fire by files, or independently of one another. In England, when the 2 rank formation is employed, the square will be four ranks deep, but with continental nations, where the 3 rank formation is employed, it would be six ranks deep; for instance, Bonaparte, while in Egypt, formed his infantry in squares whose sides were six ranks deep, in order to resist the Mameluke cavalry, while at Waterloo the English squares were four deep.

When several battalions form themselves into squares, they dispose themselves either en echelon or in two lines, each square in the first line being at some distance in front of the interval between two squares in the second line; by which means the fire of one square may defend the face of another.

Squares may be reduced to columns, and these to line, by reversing the processes above mentioned. One square consisting of several battalions is not recommended, as much time would be spent in its formation, and the safety of the troops might be endangered should they be attacked while so occupied.

A battalion in column may be obliged to engage in a street or narrow pass where deployment is impossible. In this case, if the column is advancing, the two front companies or divisions fire, the first kneeling and the other standing; after which, on a favourable occasion presenting itself, the whole column moves forward: if the column is to retire, the first division, after firing, faces outwards, half to the right and half to the left; these subdivisions file away to the rear, where they re-load; the second division fires, then files to the rear in like manner, and so on.

Evolutions of a Regiment of Cavalry.—The movements of cavalry on a field of battle, like those of infantry, consist of marches to the front or rear, in line or en echelon; deploying from open or close columns into line, and the converse.

If it be required to form a line for attack from an open column of divisions upon any particular division, those divisions which are in front go about by threes and make a wheel forward on the outward flank equal to one-eighth of a circle, and those which are in the rear wheel forward one-eighth; all the divisions being thus parallel to each other, they march in this order up to the alignment on the division which remained stationary, wheeling into it as they arrive. On the contrary, if the column be in retreat, and it be required to form a line on the defensive from an open column of divisions, suppose on the first division of the first or leading squadron, the leading squadron countermarches and all the remaining divisions make a wheel equal to one-eighth of a circle, and in this order march up and wheel into the alignment. It must be observed that the line first formed in these cases is to be at the distance of two horses' length in rear of the intended alignment, in order to allow the officers in front of each squadron to dress the troops, which they can do more correctly than the officers of divisions who are in the line itself.

To deploy in line to the front from a close column of squadrons for an attack, suppose on the second squadron; all the squadrons except this break into divisions by threes, as it is called (that is into divisions consisting of three horses in each of the two lines); the divisions of the first squadron wheel a quarter circle to the right, and march in that order till they get beyond the squadron on which the line is to be formed; the third and fourth squadrons also break into divisions in like manner, wheeling to the left, and marching till they get opposite their respective places in the intended line, which is supposed to be in front of the ground occupied by the first squadron, and into this line all the squadrons now march. But if the line be required to be formed on the rear of the regiment when in retreat, for the purpose of defence, suppose on the fourth squadron, this squadron must then change its front by a counter-march, the others break into divisions, wheel a quarter circle, and march to the left till they come opposite their proper

places in the intended alignment, into which they then march as before.

The evolutions are made as above stated when the regiment is in column with its right in front; but it is easy to apply the precepts to the contrary case.

The reason why the squadrons are made to break into divisions by threes is that, since the breadth of three horses is about equal to the length of one, each division of three can wheel within a space equal to that which it occupies in line: the practice however has been objected to on account of the extension of the files which is produced when marching in this order. Movements by the usual divisions or sub-divisions have been preferred on this account, but the former method prevails.

Evolutions of an Army.—The general principles upon which the evolutions of armies, divisions, or brigades are performed, correspond nearly to those of single battalions. When a whole line has to advance parallel to itself, one of the battalions is considered as the regulator, and all the others should conform to its movements. The commander of this battalion must therefore devote his whole attention to the preservation of the direction which has been indicated by the general commanding the army, while the flank officers of the other battalions must endeavour to preserve the regularity of their own battalions by the line of the colours.

Columns of route or manœuvre are formed of any number of battalions, each in column of companies or of sub-divisions, in rear of one another: it is then termed a mass of columns; and if the columns are at close order, the interval between every two battalions is only six paces, or the same as if all the troops were drawn up in line. If the distances of the companies are equal to one quarter of the length of their front, the intervals between the battalions are twelve paces; but when the columns are at open order, the intervals of the battalions should be equal to the breadth of the column, together with the six paces which should be the intervals between the battalions in line. Such columns as the last can instantly be thrown into line to a flank by each company making simply a wheel on its proper pivot. When a mass of columns is required to form into what is called a line of columns, the heads of all the columns must be placed in one alignment, but the distances of the several columns from one another in the direction of the line may, according to circumstances, be of any extent, from six paces (in which case the columns are said to be contiguous), to the proper distance for deployment, that is, a distance equal to the length of a column.

A column whose divisions are either at quarter distance from each other, or in close order, can always wheel into a line of columns, because each battalion, in performing the wheel, leaves room for the wheel of that which is in its rear; but a line of contiguous columns, when the depth of each battalion exceeds the extent of its front, cannot for want of room be wheeled into a single column. When such a manœuvre becomes necessary, the line of columns must open out to the right or left far enough to allow the wheel to be performed. When a line of columns is required to be changed into one column, for the purpose of performing a march towards either flank, the most convenient disposition would be that in which all the columns in the line stand with their right wings in front, if it is intended that the march should be towards the right; and the contrary, if it is to be towards the left, for then a simple wheel to the front brings the divisions into the alignment in their proper order.

When a column is on a march, the baggage should be in the rear; or if, on any account, it is placed within the line, it should be, together with the artillery which accompanies the column, in the intervals between brigades, and never between the battalions of a brigade. The preservation of the original extent of a column in front is of importance, and defiling, in order to pass an obstacle, should be avoided if possible, on account of the loss of time which it occasions; in fact, it will frequently happen that, on arriving at a stream, a ditch, or a bank, the obstacle will be more conveniently passed by extending than by contracting the front.

Echelon movements of an army are almost always those which are made when in presence of the enemy, the inequalities of ground generally preventing large bodies of troops, if it were otherwise advisable to do so, from acting against one another in continuous lines. Like the echelon movements of battalions, those of an army may be either direct or oblique: the former are executed by advancing brigades, battalions, or companies parallel to and at unequal distances from their front; and this advance may be made from the centre of the line when it is intended to refuse both wings to an enemy, or from one flank when it is intended to turn that of the enemy. The direct echelon may also be produced by posting columns in proper situations, ready for deployment, parallel to the enemy's position: the distances between the battalions in echelon should be sufficient to allow them to form squares chequerwise, so as to flank one another.

Oblique echellons of an army are formed by wheeling, and then marching in the new directions so as to gain ground obliquely towards a flank; each of the several bodies performing the manœuvre should not exceed a company, as it might be hazardous to present one flank of a large body towards an enemy in position, and thus expose the line to be enfiladed. And, as the enemy would endeavour to counteract the intended project of outflanking him, should he observe it, advantage

ought to be taken of the localities to conceal some of the divisions, and to gain points of support for the bodies placed in advance of the rest of the army. When it is intended to refuse one wing, the battalions of that wing may retreat *en echelon* as far as necessary, and the artillery of that part of the line which is stationary should be ready to enfilade the enemy on his advance towards the retiring divisions. Movements of attack may be made in columns, which should deploy in line at from 1200 to 1400 paces from the enemy; the destructive effects of an enfilading fire preventing a nearer approach in column.

Generally speaking, the most convenient order for an army, whether on the offensive or defensive, is in column, provided the columns can be covered by the ground from the enemy's artillery; since it may be readily moved up to any given point of attack, while the enemy has few means of judging where that point of attack will be.

Changes in the front of a position, when under fire, are best effected by an echelon march of companies; but when the line is extensive, the battalions which are most remote from the new alignment, and which may be attacked by cavalry during the movement, should be marched up in columns of battalions, the divisions being at quarter distances from one another.

The retreat of a line is accomplished by causing each alternate battalion to retire, perpendicularly to the front, to a certain distance towards the rear, not exceeding 200 yards, that the divisions may be able to support each other by their fires; the remaining battalions protecting the retreat of the others, and then retiring as far as the intervals between the former battalions, who then retreat still further, and so on. The intervals in the lines should be occupied by light infantry; and if the enemy should press closely, the second line of the army, after the first battalions have passed through it, must contribute by its fire to the defence of the intervals in the first line.

This retreat by alternate battalions, or by half-battalions, is indispensable when it is made over a plain; and if the retreat is to be continued, defiles and commanding spots of ground must be occupied and defended as long as possible; by degrees the bodies may diminish their fronts and form themselves into columns of march.

If a gradual retreat of the whole line is not intended, on a flank of the army being attacked, that flank only may be retired in direct echelon by alternate battalions or half-battalions, beginning with that which is at the extremity of the flank attacked; the remaining battalions then retire, still *en echelon*, thus keeping the menaced flank refused to the enemy, taking care that the distances between the corps are not so great as to render it impossible for them to defend each other by their fire. Each body must repel an attack, if made upon it by infantry, by a counter-attack; if by cavalry, it may dispose itself in a square; or a new line may be formed in the oblique position, if it be thought best thus to resist a general attack of the enemy.

The movements of the second line of an army should correspond exactly to those of the first, the two lines always preserving their parallelism and distance. The second is however frequently kept in a line of columns of battalions, and is made to move in that order even when the first line is deployed.

The most proper stations for cavalry are on the wings of an army, because troops of this class are unfit for resisting an attack; and should they be compelled to retire when placed in the centre, there would be left an interval which the enemy might immediately occupy, and from thence enfilade the wings. This false disposition was made by the French at the battles of Höchstet and Minden, and was the cause of their defeat in those actions. Cavalry are generally employed in the operation of turning a line; and it is evident that this manœuvre must be more readily made from the nearest wing than from the centre.

Manœuvres of Light Troops.—To the light infantry and riflemen, or troops acting as such, are entrusted the guard of the encampments or cantonments. When an army is on the march they reconnoitre the country, repel any parties of the enemy which might get between the columns while advancing; and they check the pursuit of the enemy in a retreat.

When a battalion is employed as light infantry, not more than one-third of the men should actually engage as skirmishers; these extend themselves in line, in two ranks, to the right and left, from some given file, at any distance which may be appointed; or, if no order is given, at the regulated distance of six paces. The rest of the battalion is divided into parties, as supports and as reserve, the supports, of which one party is usually in rear of the centre, and another is towards each flank, should be equal in strength to the skirmishers, and when the skirmishers have advanced about 200 paces to the front, these supports follow them, and are themselves followed by the reserve, at about 300 yards, the main body being about 500 yards behind. Each of the supporting bodies and the reserve should be kept in compact order; and when the skirmishers retire upon their support, they form in sections in its rear. The skirmishers advance or retire, as the case may be, in one general line, and they should avoid standing exposed if any cover, as that of a hedge, ditch, or copse, can be obtained on the ground: for this reason, when obliged to cross an open plain, their line should make a simultaneous rush towards the spots where they may fire under cover. On open ground, they fire kneeling or lying down, the front rank man discharging his piece first, then retiring in rear of the second rank and loading: as soon as he has loaded he gives the

word, ready, in a low voice, when the second rank man fires and loads, care being taken that the muskets of both ranks are not unloaded at the same time.

On the appearance of cavalry the nearest supporters and the reserve move towards the threatened part, and form squares; the skirmishers at the same time run to any cover from whence they may aid the supports by a cross fire; or run in behind the supports, and form square under the protection of their fire; or if too suddenly attacked for this, form small knots or rallying squares, by running together at convenient points round their officers.

When light troops have to advance across a bridge, or through a short defile, on arriving at the bank of the river, or at the entrance of the defile, the skirmishers lie down in line and fire; the supports, strengthened by the reserve, charge the enemy on the bridge, or in the defile, drive him back, and then form an extended line as skirmishers, while the former skirmishers pass the bridge or defile, and now constitute the supports and reserve. In retreating the supports pass first over the bridge or through the defile, covered by the skirmishers and immediately deploy, in order to act as skirmishers themselves; the former skirmishers then rapidly pass, followed by the supports, and the whole form in column in rear of the present skirmishers, who then, by their fire, protect the retreat if it is to be continued.

MANOMETER (from two Greek words—*μανός*, thin or rare, and *μέτρον*, a measure) is the name given to instruments which measure the rarity of the atmosphere or other gas. As however the rarity of a gas is proportional to its elastic force, so long as its temperature and chemical composition remain unchanged, such instruments as measure the elastic force of gases are also, with this restriction, properly termed *manometers*, and accordingly it is to the latter instruments that the term is most frequently applied, both in this country and upon the Continent.

The "statical barometer" of Robert Boyle was a manometer of the simplest kind, consisting of an exhausted glass globe suspended from one extremity of a delicate balance, and counterpoised by a metallic weight at the other extremity, the adjustment being made when the atmosphere was in its mean state of density. Any subsequent variation in the specific gravity of the air would, by a known law of hydrostatics, destroy the equilibrium, and the motion of the globe would indicate whether the variation had inclined towards an increase or diminution of density, as in the former case it would ascend, in the latter it would descend.

Captain Phipps, in his north-polar voyage, and Colonel Roy, in order to correct his barometric observations, employed manometers, which gave the elastic tension of the atmosphere. They consisted of glass tubes similar in form to thermometer-tubes, and of various sizes. Those of Colonel Roy were from 4 to 8 feet in length, with bores from $\frac{1}{16}$ th to $\frac{1}{8}$ th of an inch in diameter. The bulb and part of the tube being filled with air of known tension, and the remainder of the tube being partially occupied by a small column of mercury sufficient to cut off the communication between the internal and external air; any variation in the elastic tension of the latter, arising from change of weight, would be accurately measured by the ascent or descent of the mercurial column; for whenever the tension of the atmosphere exceeded that of the contained air, the column would move towards the bulb, and the contrary. But if the change in the tension of the atmosphere were partly attributable to a change of temperature, then the motion of the column would merely measure the difference of the variations in the tension of the internal and external air, because the tension of both would be equally affected by the change of temperature. The bulb was pear-shaped, so that the "point being occasionally opened, dry or moist air could be readily admitted, and the bulb sealed again without any sensible alteration in its capacity." ('Phil. Trans.,' vol. lxvii., p. 689.) The manometers of Varignon and Wolf were similar to the preceding.

A more convenient instrument, and one of more general use, consists of a siphon-barometer, the basin of which is enclosed air-tight in a globular or other conveniently shaped vessel, furnished with a number of cocks, by means of which and the pneumatic pump the contained gas may be removed, and other gases successively substituted in its place. If equal parts by weight of different gases be thus successively introduced, they will not be affected by any change which may take place in the surrounding atmosphere, except in so far as such change may affect their temperature; so that, providing the temperature remain constant, the relative tensions of these gases will be accurately measured by the weight of the mercurial column suspended in the longer arm of the barometer, above the level of the mercury in the basin; care being had to allow for any variation in the capacity of the receiver, arising from alteration in the level of the mercury in the basin, and likewise for the small tension always indicated by the barometer immediately previous to the introduction of a fresh gas, arising from the impossibility of forming a perfect vacuum.

If an approximate vacuum be formed in the receiver enveloping the basin of the barometer, and a small quantity of any liquid be then introduced, it will be immediately converted into vapour, and the elastic tension of this vapour will be measured in precisely the same way as that of permanent gases. The receiver is sometimes of sufficient size to contain animals and plants, the effect of which in increasing or diminishing the tension of the enclosed gas is then measured by the

rise or fall of the mercury. If this manometer be transported from one place to another, where the temperature is the same, but the force of gravity different, this variation in the force of gravity will be manifested by a corresponding variation in the length of the mercurial column; that is, if the gravity increase, the tension of the enclosed gas will be counterbalanced by a shorter column of mercury, and the contrary; but as this method of measuring the variations in the force of gravity is not susceptible of that accuracy which is attained by the employment of the pendulum, it is rarely if ever resorted to.

The exact determination of the elastic force of aqueous vapour at high temperatures being essential to the safe construction and management of steam-engines, the French government requested the Royal Academy of Sciences to institute a course of experiments, with a view to the attainment of so important an object. The care of making these experiments was confided by the Academy to MM. de Prony, Arago, Girard, and Dulong, who made their report in 1830 ('Annales de Chimie,' t. xliii., p. 74.) The manometer constructed for this purpose consisted of a straight glass tube of uniform bore, 1.7 mètres (67 inches) in length, and 5 millimètres (1.25 inches) in diameter and thickness, closed at the upper and open at the lower extremity. The capacity having been accurately determined, it was filled with perfectly dry air of known density, and enveloped in a cistern of water, which was kept at a uniform temperature. Another tube of equal bore and thickness, but 26 mètres (85 feet) in length, and open at both ends, was then erected, and the lower extremities of the two tubes were made to communicate with apertures in the opposite sides of a cylindrically-shaped reservoir, capable of holding about 1 cwt. of mercury. By means of a forcing-pump adjusted to the top of this reservoir, the pressure upon the surface of the contained mercury could be increased at pleasure; and this increased pressure, being transmitted to the lateral apertures already mentioned, would obviously cause the mercury to rise in both tubes, but to unequal heights; for in the longer tube it would rise until the weight of the mercurial column, together with that of the superincumbent atmosphere, were equal to the pressure; but in the shorter tube, only until this pressure was counterbalanced by the rapidly augmenting expansive force of the confined air, added to the weight of the small column of mercury forced into it. The expansive force of the compressed air would be measured by the difference of these two columns; and by this means, the shorter tube having been carefully graduated corresponding to pressures varying from one to twenty-nine atmospheres, the construction of the manometer was complete. The longer tube and the forcing-pump were then removed, as no longer necessary, and instead of the latter was substituted the actual pressure of steam at successively increased temperatures, the tension of which was indicated by the compression of the air in the manometer.

The French apply the term manometer to any apparatus which measures the pressure of aeriform bodies, such as the pressure-gauge of a steam-engine or of a gasometer. They distinguish three classes of manometers, namely, *le manomètre à air libre*, *le manomètre à air comprimé*, and the metallic manometer. The open air manometer consists of a glass tube of about five mètres in length, one end of which is cemented into a cast-iron cistern containing mercury. Parallel with the glass tube is a tube of iron four mètres in length, the lower extremity of which passes by a lateral opening into the mercury cistern. This iron tube is filled with water, which transmits the pressure of the steam, &c., to the mercury, the ascent of which in the glass tube marks the pressure in atmospheres and tenths. This form of instrument is not used for greater pressures than those of five or six atmospheres. In Cazalet's manometer the steam is made to act on the sectional area of the rod of a piston, the plunger of which, of much greater sectional area, presses on and so sustains in the other leg of the inverted siphon into which it plunges a mercurial column of sectional area equal to its own. The compressed air manometer is based on the law of Mariotte, that the volumes of gases are inversely as their pressures. It consists of a glass tube closed at its upper extremity, filled with dry air, and fastened securely in an iron cistern containing mercury, from which proceeds a side tube which is connected with the boiler, or vessel containing the vapour whose elastic force is to be measured. Any pressure acting through this tube on the surface of the mercury in the cistern will force it up the tube, which is graduated according to the above law, and by its indications gives the pressures put in operation.

The metallic manometer of M. Bourdon is constructed on the same principle as his metallic barometer [BAROMETER], namely, that when a tube with flexible sides and slightly flattened is rolled into a spiral form in the direction of its smallest diameter, any internal pressure on the sides tends to unroll the tube, while any external pressure tends to roll it up more closely. In this manometer the curved tube is of brass, 0.7 mètre in length, of long flattened oval section, the major axis being 11 millimètres and the minor 4 millimètres in length. To one end is attached a tube and a stop-cock for putting it in communication with a steam-boiler; the other end is closed, and carries a needle, the arrow of which moves over a graduated scale representing the tension of the vapour in atmospheres. Vapour being admitted, the pressure causes the spiral to unroll, and in doing so the needle is carried over the scale. This instrument has the advantage of being portable, and not fragile, and hence is used in connection with locomotive boilers.

MANOR (*Manerium*).

I. *Origin of Manors.*—At the time of the Norman conquest *manerius* or *manerium* (from *manere*, to dwell) denoted a large mansion or dwelling. The “manerium” of the Exchequer Domesday is the “mansio” of the Exeter Domesday, each being therefore the equivalent of the Anglo-Saxon or French term used by the officers who made the survey. [EXETER DOMESDAY.] In France the corresponding word “manoir” has never acquired any other signification than that of a mansion; and an estate possessing the peculiar incidents of an English manor never became so common in France as to require a specific name.

The modern English manor derives its origin from subinfeudation [FEUDAL SYSTEM], as it existed before the modifications of the system of tenures introduced in 1225 by Magna Charta, and the still more important alterations made in 1290 by “The King’s Statute of buying and selling Lands,” commencing with the words “Quia Emptores Terrarum,” and in 1324 by the statute ‘De Prærogativâ Regis,’ by which statutes, the process of subinfeudation, or of granting land, &c. in fee-simple, to be held by the grantee as a tenant or vassal to the grantor, was stopped.

Where a subinfeudation made by A to B extended to the whole of A’s land, nothing remained in A but a seigniorship with the ordinary feudal incidents of tenure, together with such rents or other services as might have been reserved upon the creation of the subtenure. This interest in A was a seigniorship in gross, that is, a seigniorship held by itself, unattached to any land, an incorporeal seigniorship, termed by the French feudists “un fief en l’air.” But in the case of subinfeudation of part of the land, the ordinary mode of proceeding was this:—A, a large proprietor, having a mansion and land at Dale, created a subtenure in a portion of his land by granting such portion to B and his heirs, to hold of A and his heirs, as of A’s manerium (mansion) of Dale, which words created an implied condition that B should perform the service of attending, with the other tenants of A holding by virtue of similar subinfeudations, at A’s halmote of Dale, that is, at A’s court meeting in the hall of A’s mansion at Dale (afterwards called A’s court-baron of his manor of Dale), for the purpose of deciding judicially all disputes among A’s free tenants holding of him by the same tenure as B, in respect of their lands so holden, and also all actions brought by persons claiming such lands.

Upon this subinfeudation being effected, A would continue to be the owner of the mansion of Dale and of that part of the land of Dale, of which he had made no subinfeudation, in demesne (in dominico suo),—as his own immediate property; and he would have the seigniorship of lands of which B and others had been subinfeoffed, as a seigniorship appendant or legally annexed to the mansion of Dale, and to the demesnes of Dale, of which the mansion formed part.

This conjoint or complex estate, taking its denomination from the mansion (manerium), which was considered as its head, and which, in the language of the Year Book of 14 Edward II. (Maynard, 426), “drew to itself all the appendancies,” by degrees acquired the name of manerium or manor.

A manor therefore originally consisted of lands in demesne, upon which the lord had a mansion, and to which lands and mansion, and more especially to the latter, there was appendant a seigniorship over freeholders qualified in respect of quantity of estate (that is, by a tenancy for life at the least, if not a tenancy in fee-simple), and sufficient in point of number, to constitute a court-baron. These freeholders were called vavassors [VAVASSOR], and their lands “tenemental lands,” that is, lands granted out in tenure, to distinguish them from the lord’s demesnes. These tenemental lands, anciently known by the denomination of vavassories, though held of the manor and within the seigniorship (or, as it was usually termed, within the fee) of the lord, were not considered as part of the manor; but the services issuing from such tenemental lands were part of the manor and essential to its existence.

Afterwards it was sufficient if the site of “a mansion at which the services had been reserved, or as it was called, the site of the manor, formed part of the demesnes; and, at last, this vestige of the origin of the name of the estate was dispensed with, and if the lord retained any portion of the land, so that there would be some demesnes to which the seigniorship over the freehold tenants of the manor, and the services rendered by them, might continue to be appendant, the compound estate called a manor was not dissolved, whether it could be shown that a mansion had ever stood on the part of the demesnes or lands retained, or not, and even if the lord had aliened and severed from his demesnes the spot on which the mansion had once stood.

II. *Nature and incidents of Manors.*—A manor is commonly said to consist of demesnes and services. It is quaintly, but perhaps more correctly stated by Fulbeck, that these “are the material causes of a manor;” for though there can be no manor unless there be both demesnes and services, other things may also be members and parcel of a manor.

1. The demesnes are those lands within the manor, of which the lord is seised, that is, of which he has the freehold, whether they are in his own occupation, or in that of his tenants at will, or his tenants for years. The tenants at will have either a common-law estate, holding at the joint will of the lessor and of the lessee, or a customary estate, holding at the will of the lord according to the custom of the

manor. [COPYHOLD.] The tenancy for years of lands within a manor is, in modern times, usually a common-law estate, though in the assessionable manors, parcel of the duchy of Cornwall, customary estates for years still subsist (VIII.); and where a copyholder surrenders for years, the surrenderee becomes a customary tenant for years of the portion of the demesnes so surrendered.

2. The services of a manor are, the rents, and other services, due from freehold tenants holding of the manor. These services are annexed or appendant to the seigniorship over the lands holden by such freehold tenants. The lands holden by the freeholders of the manor are holden of the manor, but are not *within*, or *parcel of*, the manor, though within the lord’s fee, or manerial seigniorship.

Copyholds, being part of the demesnes, are not held of the manor, but are within and parcel of the manor.

The demesne lands were formerly called the *inland*, and the tenemental lands, the *outland*, of the manor.

3. But though a perfect legal manor cannot exist without demesnes and services, other incorporeal hereditaments, which are not services, may be parcel of the manor, as advowsons, rights of common, rights of way, &c., and, under peculiar circumstances, even rents-seck and rents-charge.

In general, the power of holding courts of justice, whether for the decision of criminal matters or for the determination of civil rights, can be exercised only under authority derived from the crown, either by actual grant or by prescription; and in order to prevent usurpations of such a power, the crown may at any time issue process for the purpose of instituting an inquiry by what authority [QUO WARRANTO] a subject holds a court of justice. But it is a distinguishing feature of the feudal system, to make civil jurisdiction necessarily, and criminal jurisdiction ordinarily, coextensive with tenure. Upon this principle there is inseparably incident to every manor a court-baron (*curia baronum*), being a court in which the freeholders of the manor are the sole judges, but in which the lord, by himself, or more commonly by his steward, presides. The jurisdiction of the court-baron extends over all personal actions in which the debt or damages sought to be recovered are under 40s.; and real actions in respect of lands held of the manor could not have been brought in any other court, except upon an allegation that the lord of the manor had in the particular instance granted or abandoned his court to the king (*quia dominus remisit curiam*). To a quo warranto therefore for holding a court-baron, it is a sufficient answer—that the defendant has a manor. As this court was essential to the due administration of justice in questions respecting the right of property held of the manor arising amongst the lord’s tenants, there could never have been a perfect manor without a sufficient number of freeholders to constitute the court-baron, which number must consist of three, or two at the least; three being necessary where the litigation was between two of the freeholders.

4. Some things are popularly supposed to be incident to a manor, which have no necessary connection with it. Thus the ownership of wastes within the district over which the manor extends, is frequently called a *manorial right*, though the right and interest of the lord in wastes, over which no acts of ownership can be shown to have been exercised by him, rests entirely upon the presumption in favour of the lord, arising out of the circumstance of his being the present owner of the demesne lands, and the former owner of the tenemental lands which adjoin such wastes. The same presumption would arise in favour of any other owner of an extensive district. It is however true that lords of manors in their original grants, both to their freehold and to their copyhold tenants, usually reserved the waste lands, giving to the freeholders and copyholders merely rights of common over the wastes. Hence it arises that, in point of fact, manors, in proportion to their extent, frequently contain a much larger portion of wastes than other estates.

Copyholds are a common incident to the demesnes of a manor, but there are many manors in which this species of tenure does not appear to have ever existed, and many more in which it has been long extinct; and though there are now no copyholds unconnected with a manor, the custom of demising by the lord’s rolls appears to have formerly been common to every lord or freeholder who had demesnes which were held in villenage. So the right to have a court-leet is a royal franchise [LEET], under which the grantee holds a court of criminal jurisdiction in the king’s name, over the residents (residents) within a particular district. This privilege may be granted to persons who are not lords of manors; and where the grantee has a manor, the limits of the manor and of the leet are not always co-extensive.

III. *Manors, how created.*—Since the statutes of Quia Emptores and De Prærogativâ Regis no manors have probably been created; and it has been commonly said that no new manor could afterwards be created. But as a proposition of law this appears to be stated too broadly. The former statute has been held not to apply to the immediate tenants of the king, who is not one of the “magnates and other (that is, inferior) lords.” The latter statute speaks only of lands held by knight’s-service, and therefore, like the clause in the statute of wills imposing a restriction upon the devising of lands of that tenure, appears to be inapplicable since the abolition of military tenures. Besides, the statute of Quia Emptores Terrarum has been held to contain an implied exception in respect of alienations made with the licence of all lords, mediate or immediate; and in the statute De

Prærogativâ Regis we find an express exception in favour of alienations made with the licence of the king. It seems to be questionable whether, even by the common law, the immediate tenant of the crown did not incur a forfeiture by making a subfeoffment without licence. (34 Edw. III., c. 15.) It has also been objected that a court-baron is necessary to a manor, and that a man cannot, by granting lands in tail, reserving suit at his court, create a court-baron. But this objection assumes that no greater subtenure can now be created than an estate tail; whereas, *with licence*, a subtenure in fee may be created, and the holding of a court-baron seems to be incidental at common law to the signiory over tenants in fee-simple.

Practically however no entirely new manors are now created; but where, upon the partition of a manor, part of the demesnes and part of the services, including suit of court of a sufficient number of freehold tenants to constitute a court-baron, are assigned to one parcener, joint-tenant, or tenant in common, and other parts of the demesnes and services to another parcener, &c., each party has a manor, and may hold a court-baron. And it is said that if a manor extends into several townships, the lord may create separate manors by conveying the demesnes and services in township A to one, and those in township B to another.

IV. *Manors, how destroyed.*—A manor is not destroyed by the loss of those incidents which, though members, and forming part, of the manor, are not, like demesnes and services, the "material causes of a manor." Nor will the legal existence of the manor be affected by the alienation of *part* of the demesnes, or by the alienation or extinction of *part* of the services, or by the extinction of all the copyholds. But upon the alienation of all the demesnes, or the alienation or extinction of all the services, the manor ceases, and is said to be destroyed: and though any part of the demesnes, however small, will keep alive the manor, if there be sufficient services, it can exist no longer than whilst there can be found enough freehold tenants to constitute a court-baron. Thus if the lord purchase the lands of all his freehold tenants, or of all except one, or if the freehold escheat, or if the lord release or alien the services, the manor ceases to exist. So, if the lord alien the freehold of all lands holden of him by copy of court-roll, or enfranchise all the copyholders, in a manor where there are no demesnes except the copyholds. So, if he alien all the demesnes. So if, upon a partition of the manor, the demesnes are allotted to one and the services to another. But in none of these cases is the destruction of the manor absolute and irrevocable. If there cease to be any demesnes, so that the manor is turned into a signiory in gross, yet upon the event of any of the freeholds holden of the manor coming to the lord by escheat or purchase, the lands so escheating or purchased will become demesnes of the manor, as they were, before the subinfeudation of those lands, whereby they were originally severed from the manor, took place. Where a manor is destroyed by partition between co-parceners, if one die, and the other takes the share of the party dying as heir, the manor revives; but it would not be so in the case of a partition between joint-tenants or tenants in common, nor would the manor revive in the case of co-parceners if the severed portion of the manor were re-united, not by descent, but by purchase. Where all the freehold tenants have ceased to exist except one, there is no longer a complete legal manor, because there can be no court-baron; but if the remaining tenant convey his tenement in fee to different persons in severalty, as there will be now a sufficient number of freeholders holding of the manor, to constitute a court-baron, the manor will revive. But without such revival, the estate is by some lawyers considered to be still entitled to the designation of a manor, by reason of there being demesnes and a signiory appendant, though over one tenant only. (1 'Anderson,' 257.) Such an estate is however more frequently called "a manor by reputation," a vague term, applied indiscriminately to all estates which have been manors, and which indeed would be equally applicable to a property which had acquired the name of a manor without having ever been one.

V. *Manors, Customary.*—So much importance formerly attached to the possession of a principal mansion at which the services of tenants might be rendered, that a person holding lands in customary villenage might grant portions of his villenage to be holden of the grantor, for as great an estate as the grantor had, as of his mansion or manerium. The estate of the grantor, which, after this operation, would consist of the mansion and the other ungranted portions of the villenage, with the services of the grantees appendant thereto, was called a customary manor.

The estate of a person to whom the lord of a manor has granted the freehold and signiory of all the copyholds within the manor or within a certain district, has been sometimes loosely called "a customary manor." But such an estate cannot, in any sense, be said to consist of demesnes and services.

VI. *Manors in Ancient Demesne* are those manors which, though now mostly in the hands of subjects, formed part of the royal domain at the time of the Conquest, and are designated in Domesday as "terra regis." The peculiarity of these manors is, that there exists in them a particular class of tenants possessing certain customary privileges, supposed, by Lord Coke and others, to be derived from the indulgence of the crown in matters "pertaining to the king's husbandry." They were formerly called "tenants in socage in ancient tenure," but are now commonly known as "tenants in ancient demesne," a term not

in itself very accurate, since all tenants within these ancient demesne manors, whether copyholders or leaseholders, and even the lord himself, are strictly speaking tenants *in* ancient demesne. In these customary tenures the freehold is not in the lord, but in the tenant, who is therefore called a customary *freeholder*; and it does not appear to be necessary to the continuance of the manor that there should be any other freehold tenants, though lands may be held of a manor in ancient demesne by the ordinary freehold tenure, which lands are called lands in frank-fee by way of distinguishing them from the customary freeholds held by the "tenants in socage in ancient tenure," now called "tenants in ancient demesne."

VII. *Manors in Border Counties.*—The exposed state of the northern borders of England, liable to hostile incursions in time of war, and scarcely less in times of nominal peace, created a peculiar species of tenure in the manors in the four northern counties. Persons holding by this tenure are called customary freeholders; though here the *freehold* is in the lord, and the timber and mines belong to him, and not (as in the tenure in ancient demesne) to the tenants; but they are so called because they are allowed the privilege of passing their estates, as freeholders do, by feoffment and livery, a privilege perhaps derived from the irregularity with which the customary courts of the manor were held, and from the necessity of allowing persons whose tenure of land and of life was so uncertain to make immediate dispositions of their property.

VIII. *Manors, Assessionable.*—A term peculiar to that part of the domain of the Duke of Cornwall [WALES, PRINCE OF] which is situate within the county of Cornwall, consisting of seventeen manors, namely, Launceston, Trematon, Tyntagell, Restormel, Stoke-Climsland, Tybeste, Tewington, Helston-in-Kerrier, Moresk, Tywarnhaile, Penkneth, Penlyn, Rellaton, Helston-in-Trigshire, Liskeard, Calstock, and Talskydy.

The earls and dukes of Cornwall, and, when no earl or duke, the crown, have sent from time to time (commonly every seven years) certain persons commissioned to visit these manors in succession, and to *assess* the lord's demesnes, that is, to let them at such rents and upon such terms as might appear to them to be advantageous to the duchy. The courts held by the commissioners for the purpose of exercising the authority thus delegated to them were called *assessions*, or courts of *assession*. The course usually was to let the land until the next assession. From the conventions (covenants or engagements) entered into by the persons to whom those demesnes were so arrented, the interest demised was called a tenure *in convention*, and the tenants were styled conventionaries. These demises were made both to free-men and villeins; the former being called free conventionaries, the latter villein or native conventionaries. The latter class appears to have become extinct in the 16th century.

By degrees the conventionary tenants acquired an inheritable interest in the certainty of the renewal of their holdings in favour of themselves and their descendants at each successive assession. The conventionary tenant thus acquired, like a copyholder of inheritance, an interest freehold in point of duration, without a freehold tenure.

In conventionary tenements the minerals belong to the lord, and not to the customary tenant; as it was held upon a trial at bar in 1829, which lasted seven days (Rowe v. Brenton, 3 Mann. and Ryl., 133-364).

MANSLAUGHTER. [MURDER.]

MANU (a word which implies "rational," from *man*, to "understand"), according to a Hindu fiction, was the son or grandson of the creating deity of Brahmâ, the first of rational beings, and the progenitor of mankind, who thence are called Mânâvâs, or Manujâs (offspring of Manu). To this primeval sage, the father of the human race, and consequently their patriarchal ruler and legislator, is ascribed a celebrated system of religious and civil law, which in the beginning of time was revealed to him by Brahmâ, and has been handed down by tradition to the present age. In other words, the Sanskrit work now extant, and indiscriminately called Smṛiti (tradition), or Mânava-dharma-sâstra (the Institutes of Manu), is deemed by the Hindus not only the oldest but at the same time the holiest text after the Vedas. Before these pretensions of the sacred code to antiquity and authority can be duly appreciated, it will be convenient to state its contents, and to point out the leading features of a system at once so comprehensive and so complicated that it would be almost impossible to dwell upon its particular precepts without entering fully into the labyrinth of Hindu religion and ceremonies. The work is divided into the twelve following chapters:—i. On the creation; ii. On education, or on the first order; iii. On marriage, or on the second order; iv. On economics and private morals; v. On diet, purification, and women; vi. On devotion, or on the third and fourth orders; vii. On government, and on the military class; viii. On judicature, and on law, private and criminal; ix. On the commercial and servile classes; x. On the mixed classes, and on time of distress; xi. On penance and expiation; xii. On transmigration and final beatitude.

We shall not dwell on the first or last chapter; the first is occupied with a summary of the contents of the whole code, and with a problem of cosmogony, in accordance with the wild and fanciful conceptions of Hindu metaphysics and natural philosophy; the twelfth chapter contains a detailed system of metempsychosis and final punishments, closely connected with the institutes of temporal law. It is obvious that either a strict order in the arrangement of the judicial code has been neglected, or, what is more probable, the monarchical and civil

laws (vii.-xi.) have purposely been separated from the general duties contained in the first half of the work. These for the most part are of a religious character, being engrafted on the most rigid distinction of caste, and therefore totally dependent upon the hierarchical rules of the first order, by which even the minutest actions of the inferior classes are invariably to be regulated. Without entering into the mass of formalities and customs by which the main structure of the Brahminical, and in fact of every hierarchy is largely cemented, and into those generally absurd and often ridiculous ceremonies inculcated upon the different branches of society, it will be sufficient to remark that they were evidently congenial to the religious prejudices, and to the habits and disposition of the Hindus, and that most of them had long been sanctioned when the sacred code was promulgated. This is expressly asserted by the author himself, who professes to give the system of law in its full extent, and the immemorial customs of the four classes, adding that immemorial custom is transcendent law, approved in sacred scripture, and that holy sages have embraced good usages long established. The principal duties of the four classes in general are stated as follows:—

To the first, or sacerdotal order, the supreme ruler assigned the duty of reading the Veda, and of teaching it; of giving advice to kings, of sacrificing and of assisting others to sacrifice, of giving alms and of receiving gifts, of promoting justice on earth, and of procuring happiness hereafter; in short, a Brahmin must ever be intent on divine worship, devotion, austerity, and abstinence. It is only in case of need that he is allowed to support himself by tillage or traffic, but never by service for hire. Although he is by right the chief of the whole creation, and, whether learned or ignorant, must be revered as a powerful divinity, nevertheless he should constantly shun worldly honour, and rather seek disrespect and poverty.

The Kshatriya, or military class, is bound to defend the people, to read the Veda, to sacrifice and to give alms; the Vaisya caste to cultivate land, to keep herds and flocks of cattle, to carry on trade, to lend at interest, to sacrifice, to read the scriptures, and to bestow presents. The business of the fourth, or Sudra class, is only to serve the three upper orders, and chiefly the Brahmins.

Now in these four classes, which may be called the pillars of Hindu society, those only who are born of wives equal in caste are to be considered as of the same class with their fathers. But by intermixture and marriage with women who ought not to be married, and by the omission of prescribed duties, a great number of impure classes have been formed, which in their turn are obliged to perform strictly the special rules and obligations enjoined on their caste, or else they will sink to a still lower degree in the scale of human society. These mixed classes are enumerated at large in the tenth chapter, and prove a far advanced state of civilisation by the very great variety of professions which they exhibit. But as even the aboriginal tribes and the inhabitants of adjacent countries are asserted to have gradually sprung from the same source, we need scarcely remark that the institution of caste carried to this extent must be altogether imaginary; and moreover that a system of law founded on these vague and fanciful principles must be a partial and degrading one. Hence the punishments, consisting of pecuniary fines and confiscation of property, of mutilation of the body, and death, of exile and loss of caste (which is deemed moral death), are inflicted according to the privileges of the different classes; in general these punishments are slight and trifling for the highest order, but dreadfully severe and cruel for the same crimes when committed by an individual of inferior caste. Thus a soldier who defames a priest shall be fined a hundred panas, a merchant a hundred and fifty, but a mechanic or servile man shall be whipped; and while the slaying of a Sudra by a man of the sacerdotal class is exactly equivalent to the killing of a cat or dog, the murder of a Brahmin is an inexpiable crime, and he who barely assaults a priest with intention to hurt him shall be whirled about for a century in a place of future punishment, which is described as "a dark hell."

With regard to the penal provisions of the criminal law we shall only observe that in most of them the principle of retaliation has been sanctioned; for instance, whoever breaks a dam or sluice, by which an inundation would be caused (Buchanan, 'Mysore,' i., 4), shall be drowned; an adulterer shall be burned on an iron bed; a cut-purse is to lose two fingers, and "with whatever limb a thief commits the offence, even that limb shall the king amputate" (viii. 334; ix. 273, ff.). Nevertheless most of the punishments may be commuted for pecuniary fines; and in case a temporal chastisement proves unavailing, threats of future pain are often held out. A priest may by muttering imprecations and holy charms chastise those who injure him, without complaining to the king. In short, the first part of the sacred code is entirely what we should call hieratical. This character is apparent not only in its inflexible severity where religion and its ministers are concerned, and the well-calculated distinction of castes, by which a free intercourse between the members of society would be prevented, and consequently a more close dependence on the priesthood ensured, but also in the spirit of sublime devotion, of benevolence and tenderness to all sentient creatures, by which sacerdotal institutes are generally distinguished.

The second part of the code, containing the monarchical and civil laws, is more congenial to social order, and although the same spirit of hierarchy prevails, it is often checked by rules of a sound policy and of regular administration. The king, born in the military class, is

formed of particles drawn from the substance of the guardian deities; surpassing all mortals in glory, he is himself a divinity in a human shape, and consequently he must be the protector of all classes who discharge their duty (7, 4, 9, 301 ff.). "He must invariably speak truth and never transgress the rule of strict justice; but as just punishment cannot be inflicted by an ignorant and covetous king, he has to learn the science of criminal justice and of policy, the system of logic and metaphysics and sublime theological truth from learned priests, and from the people the theory of agriculture, commerce, and other practical arts." Nothing is so often and so strongly inculcated by Manu as the equity and justice of kings in protecting the property of their subjects against fraud and violence. For this purpose the prince shall appoint a governor of one town with its district, another of ten towns, of twenty, of a hundred, and above all these inferior authorities, a high officer, whom we may perhaps call a lord-lieutenant, over each thousand towns. Also, to prevent the people being oppressed, a superintendent of all affairs shall be established in every large town to inspect the inferior officers. A large number of laws for the mercantile tribe, with rigorous regulations about the sale and purchase of marketable things, about weights and measures, tolls and freights for boats passing up and down rivers: the severe punishment of robbers and of those who will not restore loans and deposits, and the most subtle definitions of the law of inheritance—all tend to show that, however restricted by the rules of caste the social and personal condition of an individual might be, his property at least was respected and held inviolable. As to the laws of succession, it is laid down as a fundamental rule, probably derived from ancient patriarchal manners, that, if possible, the whole property of the family should be kept together. Accordingly after the death of his father, the eldest son may take entire possession of the patrimony, and the others may live under him, unless they choose to separate. In this case, the widow and such persons as by crimes or mental or corporal defects are legally excluded from participation, being provided for, the heritage is divided into portions according to the minute and almost endless variety of regulations by which, owing to the real or imaginary intermarriage and mixture of classes, this part of Hindu law has become extremely abstruse and intricate. Property belonging to a sacerdotal student and a minor must be guarded by the king, until the owner shall have concluded his studentship, or until his infancy shall have ceased in his sixteenth year. No tax is levied or charge made for this trusteeship nor for any tuition whatsoever; and except custom-duties and market-taxes, the only legal tax or annual revenue which a sovereign may receive from his whole dominion through his collectors is imposed on the mercantile and agricultural classes. He may take either a twelfth part of the crops, or an eighth, and in time of distress even a fourth part, but in every respect he must act like a father to his people. (7, 80, 10, 118 ff.) Serving men, artisans, and mechanics never pay taxes, but they must occasionally assist by their labour when needed. According to a theory most rigorously supported in a rude state of feudal and despotic government, by several Hindu law-givers of modern times, and even by a passage in Strabo, the king has been declared sole possessor of the soil ('Digest of Hindu Law,' 1, 460; Strabo, p. 1030, *ἔστι δὲ ἡ χώρα βασιλικὴ πᾶσα*). But although the sovereign's right to an annual ground-rent, and his gifts of land, so often recorded in inscriptions and written documents, may originally have been founded on such a doctrine, its practical application would have proved ineffectual, and in fact it is nowhere adopted nor even mentioned by the sacred code. On the contrary, it is expressly stated as a rule laid down by ancient sages, that cultivated land shall be the property of him who has cut away the wood, or who has cleared and tilled it (9, 44). To prove the inviolability of the tenure of land, in which the proprietor is rather protected than limited by government, many special laws might be produced, such as those concerning landmarks and boundaries, the common ponds by which the fields are watered, the punishment inflicted on herdsmen and owners for injuring cattle; and so far is the agricultural tenant from being disturbed in his possession, that even if land be injured by his neglect, he shall only be punished by a heavier tax.

The most striking feature by which, on the whole, and notwithstanding its many glaring defects, this code is distinguished, is the rigour and purity of its morals. A complete system of ethics might be gathered from the scattered moral sentences, of which we subjoin the following few examples. "Let not a man be querulous, even though in pain; let him not injure another in deed or in thought, let him not even utter a word by which his fellow-creature may suffer uneasiness (2, 161). Let him bear a reproachful speech with patience; let him speak reproachfully to no man; with an angry man let him not in return be angry; abused, let him speak mildly (6, 47). Let him say what is true, but let him say what is pleasing; let him speak no disagreeable truth, nor let him speak agreeable falsehood (4, 138 ff.). Though oppressed by penury, in consequence of his righteous dealings, let him never give his mind to unrighteousness (4, 171); let him be firm in his contentment and check all desire of acquiring more than he possesses, for happiness has its root in content, and discontent is the root of misery (4, 12). A wise man should constantly discharge all the moral duties, though he perform not constantly the ceremonies of religion (4, 204); he should act without any view of reward, and constantly shun religious hypocrisy, for he who describes himself to

worthy men in a manner contrary to truth is the most sinful wretch in the world; he is the worst of thieves, a stealer of minds (4, 255). Even here below an unjust man attains no felicity, nor he whose wealth proceeds from giving false evidence; for the soul itself is its own witness: offend not thy soul, the supreme internal witness of men. The sinful have said in their hearts 'No one sees us.' Yes, the gods distinctly see them, and so does the spirit within their breasts (4, 170; 8, 84). He who perseveres in good actions, in subduing his passions, in bestowing gifts, in gentleness of manners, who bears hardships patiently, who associates not with the malignant, who gives pain to no sentient being, obtains final beatitude (4, 246; 12, 10). Single is each man born, single he dies, single he receives the reward of his good, and single the punishment of his evil deeds. When he leaves his corpse, like a log or lump of clay on the ground, his kindred retire with averted faces, but his virtue accompanies his soul" (4, 240). The principal moral duties in general are summed up in the following passage: "The avoiding of all injury to animated beings, veracity, the abstaining from theft and from unjust seizure of property, cleanliness and command over the bodily organs, form the compendious system of duty which Manu has ordained for the four classes" (10, 63). To conclude with the words of Sir William Jones: "The work contains abundance of curious matter, extremely interesting both to speculative lawyers and to antiquaries, with many beauties which need not be pointed out, and with many blemishes which cannot be justified or palliated; it is a system of despotism and priestcraft, both indeed limited by law, but artfully conspiring to give mutual support."

The time at which the laws of Manu were composed is wholly uncertain, and it was only from conjecture that the eminent Sanscrit scholar whom we have just named fixed the 12th century B.C. as the probable epoch of their composition. Generally speaking we may safely pronounce it the code of an already refined and enlightened people, and the work itself bears ample testimony that a very advancing degree of civilisation had been acquired by the Hindus when these laws were promulgated. But what is most important, is that the burning of widows is totally unknown: on the contrary, a widow is legally bound to devote herself to pious austerity, and may even be lawfully married to the brother of her deceased husband, as she could marry any other man during the reign of king Vena (3, 173; 5, 157). Now the duties of a Satti, so minutely detailed in works of later date, could not possibly be omitted in a sacred code of law, and therefore the work seems at least anterior to the invasion of India by the Macedonians, who were fully acquainted with these horrid sacrifices.

The learned Hindus agree that many laws enacted by Manu were confined to the first three ages of the world, and have no force in the present age; some of them have been abolished or modified by subsequent Hindu lawgivers, according to whom the work is rather to be honoured than to be strictly followed. In fact for a long time it has formed only a very small part of the juridical system, and may be considered as the oldest text-book of law extant, or as the Hindu 'Institutes,' preparatory to the copious 'Digests,' 'Pandects,' and other legal works now in use among the different juridical schools in India. (Ellis, in 'Madras Transactions,' vol. i., and Sir Thomas Strange, 'Hindu Law, principally with reference to such portions of it as concern the Administration of Justice in the King's Courts in India,' Lond., 1830.)

The 'Institutes' of Hindu law, or the 'Ordinances of Manu,' were verbally translated from the original by Sir William Jones, 1794. The Sanscrit text with the gloss of Kullûkabhatta was published at Calcutta in 1813, and a new edition of the metrical text, together with Sir William Jones's translation, carefully collated with the original, was prepared by Sir Graves Haughton, 1822, 1825. Another valuable edition was published in Sanscrit, with select notes and various readings, at Paris, in 1830, and a French translation with notes and explanations, both by Loiseleur des Longchamps, at Paris in 1833.

MANUMISSION. [LIBERTINUS; SLAVE.]

MANURE. Every substance which has been used to improve the natural soil, or to restore to it the fertility which is diminished by the crops annually carried away, has been included in the name of manure. Thus chalk, marl, clay, and even sand, when added to the soil for the purpose of improving its texture, have been called manures; and some confusion has arisen in our ideas in consequence of applying the same word to signify things which are essentially different. The French have a term by which they distinguish the substances which merely improve the mechanical texture of the soil from those which act more directly in nourishing the plants which grow in it. The former of these they call *amendements*, and the latter *engrais*.

It is well known to all practical agriculturists that the texture of the soil and the proportions of the earths of which it is composed are the first and most important conditions of its productive powers. When there is a good natural loam which retains moisture without becoming wet or overcharged with it, and permits the influence of the atmospheric air to pervade it, the crops cannot fail to be more certain and remunerating than in loose sands or tenacious clays, however rich they may be in those substances which are supposed to supply the elements from which the juices of plants are chiefly composed. But, at the same time, it is equally true that the best texture of soil will not pro-

duce good crops for any length of time without the help of some other rich manure to recruit the loss produced by vegetation.

The various means of improving the texture, such as tillage and the mixture of earths, are treated of separately. [LOAM; MARL; SOIL; TILLAGE.] We shall here confine our observations to that class of manures which stimulate or enrich the soil.

There are some substances which evidently belong to both classes of manure. Of these, lime, either in its caustic state of quick-lime or its milder form of a carbonate or chalk, is the principal. Lime, being an earth less porous than sand, and more so than clay, has an improving effect on soils in which either sand or clay prevails; but it has also a chemical effect as an alkaline earth; and, considered in this light, it acts on the soil in a peculiar manner, and greatly assists the effect of enriching manures, which are all of animal or vegetable origin.

Lime as a manure acts most powerfully in its caustic state—that is, when deprived of the carbonic acid which is generally united with it. The carbonic acid is expelled by the heat of the kiln, and limestone is by this means reduced to the state of quick-lime, in which it has so strong an attraction for moisture and carbonic acid, that, if it be left exposed to the atmosphere for any length of time, it absorbs both from it, and gradually returns to the state of hydrate and carbonate, or lime united with water and carbonic acid, with this difference, that it is now a fine impalpable powder, instead of a hard stone.

Among the purposes it serves, and besides its use as a direct food of plants, are those comprised in its relations to the dormant and mischievous ingredients of soils; its power to detach serviceable alkaline matters from useless positions in the soil; its power to induce the decomposition of vegetable matter there; its power to decompose and render harmless mineral and metallic salts of a mischievous character; its uses in detaching ammonia from comparatively insoluble compounds of it, and so presenting portions ready for immediate use by the plant; its influence in possibly increasing the power of soils to absorb ammonia from the air.

Besides all this, its influence on the texture of the soil, on the growth of weeds, on the general fertility of the land, on the growth especially of particular crops, on the health and soundness more especially of the turnip crop, should be also named.

The use of frequent limings in small doses, as compared with larger dressings at longer intervals, depends on the quantity of vegetable matter in the soil, but the larger dressings are generally to be preferred, on the grounds that in practice the full influence of a liming is not seen until after several years, and that the abundant fertility which, when lime is properly used, is consequent upon its use, may, when rightly managed, be made to reproduce itself, and so become permanent. The abuses to which it is liable are, chiefly, its application to soils deficient in vegetable matter, and its application along with manure rich in ammoniacal matters. But a distinction may be drawn between rotten dung and recent farm manure in this respect,—the application of hot lime along with the former being wasteful, but along with the latter by no means uneconomical. There are many modes of applying lime, as slaked or unslaked,—in compost with vegetable matter of any kind, or directly to the land, ploughed in deep or shallow, in quantities of 40 or of 240 bushels per acre,—previously to a corn crop or a green crop,—on a corn or clover stubble, &c. One of the best rules of practice is, to apply it where there is the greatest quantity of undecomposed vegetable fibre in the soil; and, acting on this rule, the best time in the rotation for the application of lime is on the clover stubble or the grass layer previous to ploughing it up for a grain crop.

The use of quick-lime in rendering inert vegetable fibres soluble, and hastening the decomposition of animal substances, is of the greatest importance in agriculture. Substances may be rendered highly enriching in a short time, which, without it, would have lain long dormant in the soil or the dung-heap. Its effects in this way will be more particularly noticed when we treat of composts.

Wherever there is peaty matter in the soil—which, owing to the tannin principle which it contains, is, by itself, perfectly incapable of putrefaction—lime is the true remedy. On the other hand, in a very stiff clay, chalk or lime will render it much more porous, and admit the influence of the atmosphere; it will correct acidity, and assist the nutritious effects of animal and vegetable manures. Quick-lime spread on a soil abounding in vegetable matter will make it active by dissolving the half-decomposed fibres and converting them into a soluble mucilage: being extremely minutely divided by its property of attracting moisture rapidly, a very small quantity produces an immediate effect. Hence it is generally spread over fallows or clover-leys, which are preparing for wheat-sowing. If it were put on the land long before the seed is sown, it would have lost its chief and immediate power by attracting carbonic acid and returning to the state of carbonate or chalk, and all the expense of burning would be thrown away, except as far as it has thoroughly pulverised it. But frost does this with chalk spread before winter at a much cheaper rate; and a good dressing with chalk will last in the soil, and its effects be preserved, many years after all the lime would have disappeared. It is therefore a matter of mere experiment and calculation whether it be more profitable to put ten waggon-loads of chalk on an acre of stiff clay, or one or two waggon-loads of quick-lime. If the soil be very tenacious, the chalk will probably be the most profitable in the end as well as the cheapest; but for a few crops

the lime may appear to have the advantage. Everything depends on situation, and the comparative facility with which lime and chalk can be procured.

On poor sands chalk will be found to produce a greater and more permanent improvement than the same value in lime, which, unless it be mixed with clay or vegetable substances, will not be of great use on such soils. When marl can be procured, or clay and chalk, these will be the best correctives for the porous nature of sand, whether mixed by nature or artificially. But marls are chiefly "amendments," and as such will be noticed separately.

It may however be mentioned here, that experience in the use of lime has varied exceedingly owing to two causes; one of which is that limes vary exceedingly in their qualities, and the other, that crops vary exceedingly in their need of lime. The latter of these particularly points to the use of lime as being directly the food of plants, and thus more influential for one crop than another. On the former we may merely state that analyses of lime from quarries in different parts of the island, show that the quantity of lime present varies from 60 to nearly 100 per cent. And an even more valuable ingredient than lime in certain limestones, namely, phosphate of lime, certainly adds largely to the fertilising influence which certain limestones exhibit. Thus in Connemara. Mr. Whitwell of Kendal has had various limestones analysed, with the following results:

	1.	2.	3.	4.	5.	6.	7.	8.
Phosphate of lime . .	7.16	13.8	3.5	14.8	8.5	8.3	13.7	2.0
Silica	..	46.5	82.3	20.2	2.6	41.4	8.4	44.0
Sulphate of magnesia .	..	3.0	..	..	..	0.9	..	..
Chloride of sodium . .	..	2.0	..	..	..	..	..	..
Potash	..	5.0	..	..	4.6	..	..	..
Carbonate of lime . .	..	..	8.0	43.8	49.3	..	74.3	..
" magnesia . .	..	31.8	4.2	21.2	35.0	49.4	3.6	5.0
Moisture	..	..	2.0	..	..	..	..	..

It is plain that differences of this kind must produce very great differences indeed in the fertilising influence of the lime we apply. A limestone containing only 68 per cent. of lime, such as some of them near Dublin, will be of less value than a Durham limestone containing 94 per cent. (just as 68 is less than 94) in respect merely of the effect of the caustic calcareous matters on the soil; but if, apart from this mere carbonate there be present a phosphate in any quantity, an effect of an altogether different and valuable kind must follow its application. The mineral phosphate which, while in the masses of the rock, would be comparatively useless, must, when broken down to powder as by burning and slaking the limestone rock, it becomes, be so laid open to the influence of the solvents of the rain and air, as to act upon the plants like a dressing of bones. Then again, consider the effect of a large quantity of magnesia, which when caustic acts more slowly but more persistently—and you cannot doubt that the composition of the limestone you employ must be looked to for much of the explanation of the results of its application.

But apart from the general influence of lime on the soil, there is to be considered the relation in which it stands to the several crops the farmer cultivates.

Immense differences exist among our agricultural crops as regards the quantity of lime which they contain. Thus the ash of wheat-straw contains 6 per cent. of lime, of barley-straw 8 per cent., of rye-straw 9 per cent., and these crops accordingly do not take more than 10 to 15 lbs. of lime out of an acre by the growth of an ordinary bulk. Bean-straw on the other hand, or rather the ash of bean-straw, contains 21 per cent. of lime, the ash of the pea 55 per cent., of the vetch 38 per cent.—much larger quantities, and so an ordinary crop of beans and peas respectively will take by means of the one 38 lbs., and by the means of the other 190 lbs. of lime from the acre. Both of these crops therefore, on the ground of direct use of the lime for food, require a larger quantity of calcareous matter in the soil.

Take now the case of some of the root crops: we have in turnips, bulb and top, respectively, lime to the extent of 11 and 23 per cent. of their ash respectively; in the case of mangold a smaller quantity, namely, 3 and 8 respectively; in the case of the potato, 2 and 17 per cent. respectively; in the case of the carrot, 8 and 32 per cent. respectively; in the case of lucern again, which especially prospers on calcareous soils, one-half of its ash is lime. An examination of the ash analyses of plants shows the composition of the crops which they indicate to tally with agricultural experience as to the character of the soil they prefer. Thus the ash of the lucern contains 50 per cent. of lime, and that of sainfoin 29 per cent. These figures accordingly prove that the influence of lime as a manure does to some extent depend upon its power to supply plants with direct food.

We turn now to the more direct manures—those which really contribute the bulk of those materials towards the growth of plants in which the natural soil and air, the only other sources of nourishment open to them, are deficient.

The first and most important class of manures are the excrements of animals. The peculiar property of earth in absorbing putrid effluvia and removing disagreeable smells, appears an indication of nature to

lead us to bury putrid animal substances, of which the excrements and dead carcasses of animals are the most numerous and obvious. It would require no length of experience to show that wherever this is done vegetation is more vigorous. There is therefore another motive for burying dung than merely to get rid of a disagreeable substance. From the most ancient times of which there are any records, the dunging of a field has been an important part of cultivation. The preparing of the dung of animals, so as to render it more efficacious, is a later improvement, and has not yet attained the perfection of which it is capable, unless it be so in China, of which we read wonderful accounts. The fresh dung dropped on the ground, far from improving the herbage where it has fallen, appears to injure it, and render it unfit for cattle to eat; when it gradually disappears, and not till then, the spot is restored to its former verdure. But if the dung be dug into the ground and covered with earth, the fertilising effect will be immediately perceived. This is a sufficient lesson to the husbandman to make him bury the dung as soon as possible. But this not being always practicable, it is collected in heaps until it can be carried to the land prepared for its reception by ploughing or digging. By mixing the straw, which has served as litter to cattle, with their dung, the quantity is increased, and by allowing this mixture to heat and putrefy, a greater quantity of manure is produced. This is probably the history of the dunghill. In the making of a dunghill, experience has taught methods which accord well with what science might have taught. The manure must be soluble before it can be effective; this solubility can only be produced in the more solid portions, such as the straw, by putrefaction, which the dung promotes when duly moistened. The exact moment when it is most advantageous to bury it in the ground, in order to its greatest immediate effect, seems not yet fully decided. Some let the decomposition go on until a great portion of the heap is converted into a black, tough, greasy substance, which, from early association, gives the idea of richness. It is no doubt a powerful manure which acts speedily, but is it the most economical? This may be disputed. A great portion of the substance must have been resolved into gases, which fly off and are lost. The remainder, evidently carbonaceous from its colour, has acquired too much of the appearance of charcoal to be very efficient; and it is only the exuding juice which is immediately fertilising. The most experienced farmers agree, that whenever the brown colour of a dunghill verges towards a black, the dung has lost something of its value, besides the diminution in its bulk by dissipation. The best state in which dung can be carried to the land, for an immediate as well as permanent effect, is when the straw is so rotten that it readily breaks into short pieces, without having entirely lost its form: it should then be of a brown or mahogany colour, uniform throughout the mass. Whenever dung is mentioned by foreign agricultural writers, it is generally understood to be in this state, which in English is called short dung. It must however be admitted that farm practice is more and more sanctioning the doctrine of the chemist, that it is true economy to bury manure as soon as we have it.

Autumn application of fresh dung is found more efficient and economical in the long run than the ordinary wasteful management of the dung in heaps. Nevertheless, as manure is wanted for the land at different seasons, it is of consequence that the dung from the yards and stables should be collected in such heaps, and managed so as to be in the exact state which is thought most advantageous at the time when it is carted on the land. To effect this some attention is required. The oldest portion must have its putrefaction retarded, and the newest accelerated, to bring them both to the same state. This is easily done. If a certain thickness of dung is kept trodden down by the cattle, it will be a long time before it decomposes, nor will it do this without being turned over to expose the under portions to the air. If, on the contrary, it be carried out into a heap in a loose state, and occasionally turned over and moistened when it appears dry, it will heat and be ready in a very short time. When a sufficient quantity of short dung can be carried to a field prepared to receive it, and immediately ploughed in with a shallow furrow, it will soon incorporate with the soil, and afford a succession of soluble matters, which will give regular nourishment to the plants. This is said on the supposition that the soil is in that state when it only requires replenishment, and has a texture favourable to the crops raised upon it. In poor sands or wet clays some modification in the state of the dung may be necessary.

In speaking of dung, we have not said anything of the different kinds of dung produced from different domestic animals. In some cases it may be advantageous to keep these separate: for instance, the dung of cows from that of horses; of cattle feeding on oil-cakes or grain, with or without turnips, and those fed on straw or refuse hay only. Cow-dung, when in a fresh state, is thought best for light soils, and horse-dung for cold heavy soils. But in general a mixture of the dung of all the different animals kept on a farm with all the straw that can be afforded, will give a manure of an average strength, which may be used upon all kinds of land; with this difference, that for light soils it should be more decomposed than for the heavy, and also ploughed in deeper; for the air penetrates the light soil to a greater depth, and sooner acts on the manure. In heavy land the straw, if not so much decomposed, will form cavities to let in the air, and facilitate the disintegration and tilth of the soil. All this is well known to most

farmers, but not always strictly attended to. It is better to manure slightly and often than to put on a large quantity at once, except for some particular crops, which require a rich earth and consume much manure, such as potatoes, mangold-wurzel, and Swedish turnips. Any one who has raised the above-mentioned roots with the usual manuring, and drawn them off the land to be consumed elsewhere, will acknowledge that his subsequent corn was far inferior to that which had succeeded beans, tares, or clover, with the same quantity of manure.

One chief use of cattle on an arable farm, besides those which are necessary for the operations of husbandry, is to produce manure for the land. In present times of high priced butcher's meat, cattle will more than repay their food and the expense and risk attending their keep. But even though there were a moderate loss, they must be kept, when manure cannot be purchased; and a portion of the land must be cultivated solely for the maintenance of cattle. In some poor soils one-half of the land is not too much to produce manure sufficient for the other half. The loss, if any, on the cattle must be repaid by the increase of the corn crops. Manure is to a farm what daily food is to an animal; it must be procured at any sacrifice. It is better to let land remain uncultivated in rough pasture, as was once the case with a great part of Britain, and is still the case with extensive tracts on the Continent, than to break it up without having the means of manuring it. A few crops may be obtained at first, but the land is deteriorated for ever after, and what has been obtained from it is dearly paid for.

Various means have been adopted to increase the quantity and efficacy of manure. The simplest is to increase the number of cattle, and husband their manure. It is evident that to let cattle run in loose pastures is a great loss, not only on account of the dung which is dropped, and more than lost, but also the urine, which contains the very essence of manure. In all countries where stall-feeding is practised, the lands are highly manured, and the crops more certain and abundant. With this system is connected a much more economical management of the manure, either by keeping the litter and more solid parts of the dung separate from the urine and liquid parts, which are collected in large reservoirs, and used in the liquid state, or by letting the animal remain loose in a pen or box, into which litter is daily put, so that it accumulates under the animal and absorbs the whole of the solid and liquid excrement. The liquid manure system is not gaining ground in farm practice, and it seems to be generally allowed that the best mode of saving it is in the litter of box-fed cattle; the dung thus formed containing the whole of it, in a form to which the ordinary practice of the farm is already adapted. A word or two must nevertheless be said on the uses of liquid manure.

Notwithstanding some apparently contradictory opinions, it is pretty generally acknowledged by those who have had long experience of its use, that urine and similar animal substances have a more powerful effect on the soil, when they have undergone a certain degree of putrefaction, than when they are used in a fresh state, and that this is produced with the least loss of substance when the liquid has been confined in close vaulted cisterns which admit the external air only partially. On light soils this liquid has a most fertilising effect, if it is used frequently in small portions at a time. On very heavy soils this effect is not so apparent, and for such soils the liquid is accordingly mixed with sand or any light earth before it is applied; or, instead of using it at once upon the land, it is poured over the litter, which has been collected in a heap or in a yard, after having served for the cattle. This litter, having been deprived of the urine which would otherwise have mixed with it, would rot very slowly and produce a very inferior kind of manure, unless it were moistened, and fermentation were excited by pouring the half-putrefied urine over it. It may be objected that if the urine is only collected to moisten the straw which has served as litter, it would be as well to let it be mixed at first, without the trouble of pumping it up and the expense of a cistern to hold it. But we shall soon see that there is a very wide difference. In the common mode of collecting farm-yard dung, the straw is very unequally impregnated with animal matter: at one time it will contain a large portion and run rapidly into fermentation; at another, there will be so little, that it is with difficulty that heat is excited in it. By separating the urine and litter, the straw will go much further, and can be mixed with the urine at the most advantageous time; thus it forms a much richer manure in a smaller compass, from not being so much diluted with water. Should there be a deficiency of straw, earth or sand will supply its place, in as far as soaking up the rich juices; for the addition to the manure from the decomposition of the straw itself is very small in proportion to that which animal juices afford. If the liquid is collected from a stable or a yard where cattle are kept as soon as it is produced, and is carried off into a cistern, there will be a much better and drier bed left for the cattle, especially if the rain be kept off by light shades. When the litter is soiled to a certain degree, it may be removed to a heap in a proper place, where its conversion into rich dung may be effected by the addition of putrefying urine, than which nothing will so soon rot vegetable fibres, if the air be admitted to the heap. The portion which is not wanted for some time may be left to decompose more slowly; and as the time approaches when it is wanted for the land, it may be managed so as to be in that state which experience has shown to be most effective in the improvement of the crops.

There is some appearance of certainty and regularity in this mode of making a dunghill, which there scarcely is in the common practice of accumulating straw, dung, and urine without any regularity in a farm-yard, turning it over when the cattle leave it for the pastures, and carrying so many cart-loads per acre on the land to be manured, without any measure of its comparative strength. One portion is often almost burnt black, and another appears like the fresh litter of the stables, not being even thoroughly soaked with moisture. It is true that good farmers pay more attention to their dung-heaps, and endeavour to carry out the manure in a proper state; but how much more readily would this be accomplished by the help of a large cistern full of the richest animal matter in a state of partial putrefaction. In situations where straw bears a high price, it may be doubtful whether a cistern might not permit a considerable profit to be made by the sale of a portion of the straw, without any diminution of the manure required for the farm, since for light soils the liquid might be used alone, and for stiffer soils it might be mixed into a compost with earth, chalk, and any kind of refuse vegetable matter of less value than straw. It was an opinion expressed by a celebrated agriculturist* to the late Mr. Rham, that he considered the use of straw in dung to be merely as a sponge to hold the liquid animal matter in its pores or tubes. In fact, straw or old thatch merely rotten by long exposure to air and moisture is of little or no value as a manure, although it will sometimes produce good potatoes, by rendering a stiff soil pervious and porous; but, in a light soil, a gallon of urine is worth ten times its weight of rotten straw. This doctrine may appear strange to some agriculturists, but it will bear the test of experiment.

It is well to add here the conclusion to which Dr. Völcker's researches into the composition and management of yard manure have led him. We extract them in an abridged form from his papers in the 'Journal of the Agricultural Society.'

"Perfectly fresh farm-yard manure contains but a small proportion of free ammonia.

"The nitrogen in fresh dung exists principally in the state of insoluble nitrogenised matters.

"The soluble organic and mineral constituents of dung are much more valuable fertilisers than the insoluble. Particular care, therefore, should be bestowed upon the preservation of the liquid excrements of animals, and for the same reason, the manure should be kept in perfectly waterproof pits, of sufficient capacity to render the setting up of dung-heaps in the corner of fields, as much as it is possible, unnecessary. Farm-yard manure, even in quite a fresh state, contains phosphate of lime, which is much more soluble than has hitherto been suspected. The urine of the horse, cow, and pig, does not contain any appreciable quantity of phosphate of lime, whilst the drainings of dung-heaps contain considerable quantities of this valuable fertiliser. The drainings of dung-heaps, partly for this reason, are more valuable than the urine of our domestic animals, and therefore ought to be prevented by all available means from running to waste.

"The most effectual means of preventing loss in fertilising matters is to cart the manure directly on the field whenever circumstances allow this to be done.

"On all soils with a moderate proportion of clay, no fear need be entertained of valuable fertilising substances becoming wasted if the manure cannot be ploughed in at once. Fresh, and even well-rotten dung contains very little free ammonia; and since active fermentation, and with it the further evolution of free ammonia, is stopped by spreading out the manure on the field, valuable volatile manuring matters cannot escape into the air by adopting this plan. As all soils with a moderate proportion of clay possess in a remarkable degree the power of absorbing and retaining manuring matters, none of the saline and soluble organic constituents are thus wasted, even by a heavy fall of rain. It may, indeed, be questioned, whether it is more advisable to plough in the manure at once, or to let it lie for some time on the surface, and so give the rain full opportunity to wash it into the soil.

"It appears to me a matter of the greatest importance to regulate the application of manure to our fields, so that its constituents may become properly diluted and uniformly distributed amongst a large mass of soil. By ploughing in the manure at once, it appears to me, this desirable end cannot be reached so perfectly as by allowing the rain to wash in gradually the manure evenly spread on the surface of the field."

Among other conclusions regarding the common management of dung-heaps to which Dr. Völcker leads us, are the following: During the fermentation of dung, the phosphate of lime which it contains is rendered more soluble than in fresh manure. In the interior and heated portions of manure-heaps, ammonia is given off; but, on passing into the external and colder layers of dung-heaps, the free ammonia is retained in the heap.

Ammonia is not given off from the surface of well compressed dung-heaps, but on turning manure-heaps it is wasted in appreciable quantities. Dung-heaps, for this reason, should not be turned more frequently than absolutely necessary.

If rain is excluded from dung-heaps, or little rain falls at a time, the loss in ammonia is trifling, and no saline matters of course are re-

* Mr. De Fellenberg, of Hofwyl, near Bern, in Switzerland.

moved; but if much rain falls, especially if in heavy showers, upon the dung-heap, a serious loss in ammonia, soluble organic matter, phosphate of lime, and salts of potash is incurred, and the manure becomes rapidly deteriorated in value, whilst at the same time it is diminished in weight.

The worst method of making manure is to produce it by animals kept in open yards, since a large proportion of valuable fertilising matter is wasted in a short time; and after a lapse of 12 months, at least 2-3rds of the substance of the manure is wasted, and only 1-3rd, inferior in quality to an equal weight of fresh dung, is left behind. The most rational plan of keeping manure in heaps appears to be that adopted by Mr. Lawrence, of Cirencester, and described by him at length in Morton's 'Cyclopædia of Agriculture,'—which consists essentially in adding each day's store to a narrow heap, and covering it with earth at once, completing the heap as you go.

The great use of liquid manure on light soils is to impregnate them with soluble matter, which being diffused through their substance, supplies nourishment to the roots of plants, wherever they may shoot out. It may be applied to the land at any time before the seed is sown, and soon after, when the blade springs up or the seed begins to form; in short, whenever the plant requires fresh nourishment, or when that which existed in the soil is diminished. Without liquid manure, the poor silicious sands of Flanders could never be cultivated, much less produce crops which vie in quantity and quality with those on the best soils. The quantity of farm-yard dung, in a very rotten state, which this soil would require according to the common system of manuring, could never be produced by all the straw which can be raised upon it in its first state of cultivation. But cattle produce urine, and this produces roots for cattle. The great effect of liquid manure has set the farmers on finding some artificial substitute for the simple urine and diluted dung of cattle. Such substitutes are obtained by mixing all kinds of refuse animal matter with water, and inducing putrefaction. The emptyings of privies from towns is scarcely a substitute; for it is the same as the liquid from the stables in a more concentrated form; but the refuse of oil-mills and various manufactures, when diluted and mixed with a portion of putrid urine, soon become assimilated to it. This becomes a branch of trade in those countries where nothing will grow without manure, and is a resource where an increasing population demands the cultivation of inferior soils to supply the necessary increase of food, as well as an increase of produce from those which are naturally fertile.

The increase of manure by the formation of *composts* is well known in many parts of Britain, and by their means the land has in many districts being rendered much more productive. The fundamental principle upon which composts have been made, is that of impregnating portions of earth with those parts of the dung of cattle, which, from want of management in the common dunghills, would have been dissipated and lost; and also accelerating or retarding the decomposition of animal and vegetable substances by the addition of earths, such as chalk, marl, clay, and even sand, according to the nature of the soil on which the compost is to be used. All solid manure which is to be ploughed into the ground should contain certain parts already soluble in water, which promote vegetation: while other portions should be in a progressive state, so as to afford a succession of soluble matter by a gradual and slow decomposition.

Liquid manure, however active and immediately effective, soon loses its power; whereas solid dung, well prepared and ploughed into the ground, will last for several crops. It is the judicious use of both these manures, conjointly, which has the best and most permanent effect. The dung or compost, having been ploughed in well, requires some time before it can have any direct effect on the germination of the seed or the nourishment of the plant. The liquid, on the contrary, acts from the moment it is poured on the surface. It is the milk of the young plant, which thrives upon it and stretches out its fibres through the earth, till it reaches the dung, which is now in a proper state to supply the more vigorous roots with sufficient nourishment. It is evident that the growth must be more rapid and regular, and not so liable to be checked from want of proper nourishment, nor are the young roots in danger of perishing by being too soon exposed to the immediate contact of rank dung. Every exertion should therefore be made by the industrious husbandman to increase the quantity and improve the quality of every species of manure both solid and liquid: and here careful experiment can alone be depended upon.

In the formation of composts the principal objects are, to regulate the decomposition of the organic substances, and to increase the bulk of the manure by means of less expensive materials than straw. For these purposes lime or chalk is generally used: the former, in its caustic state, to accelerate the decomposition of fibrous matter; the latter to add to the mass, and absorb any portion of acid, which is always produced in a certain stage of the fermentation. The mode of doing this is so generally known, that it is needless to describe it: we shall only observe that the stiffest clay may be used with advantage in composts, where better soil is not at hand; and for light lands, the stiffer the clay the better, provided it be thoroughly incorporated with the manure. The most useful material, under proper management, is vegetable soil or turf. This may be laid in layers with quick-lime and earth; the whole being well soaked with liquid manure. If any kind of vegetable matter, such as fern, pond-weeds, &c., can be added, it will

be so much the richer. The lime and urine acting decompose and transform it, the woody fibre is dissolved, and the whole mass, when turned over and well mixed, becomes a very rich earth, which, being spread on the land and slightly ploughed or harrowed in, greatly enriches its surface. By this means many poor soils may be improved, where the cultivation is not sufficiently extended to produce straw.

Although bones have been treated of in a separate article [BONES], it may be proper to mention here, that if some easy means of dissolving their substance were discovered, they might be made of much greater use than they now are. At present they are put in with the seed in a broken state, and as they remain a long time undecomposed in the soil, their effect, after the first crop, is scarcely perceptible, unless a very large quantity is used. By mixing dissolved bones in a liquid state with earth, almost all the component parts of urine would be there.

[We leave the preceding sentence as written many years ago by Mr. Rham, that he may have the credit of so early a prediction of the result which has actually followed the discovery of the method here discussed. In the article on BONES, Baron Liebig's method of dissolving them, which is now in universal practice, is described.]

Besides an immense number of waste substances now used in manure, we have, in guano and other imported fertilisers, means of replenishing our soils of which the agriculturists of thirty years ago knew nothing, and to some of them we must now make some reference. But, first, it may be named, that the ashes of vegetable substances which have been burnt are very effective in stimulating vegetation. They are chiefly used as a top-dressing on young clovers and grasses; and wherever there is an appearance of sourness in the grass wood-ashes are of great use. It is however seldom that wood-ashes are used as manure until the greater part of the alkali has been extracted; but when the surface of the land is pared off, and the dry sods are burnt, the ashes which result from this operation are very effective in producing a good crop without any other manure. [PARING AND BURNING.] The refuse ashes from bleachers' and soap-boilers' premises have still some portion of alkali in them, and, as they contain lime and other earths in a very divided state, their effect on the soil is very perceptible. Sea-salt has been extolled and decried at different times, owing probably to the different circumstances under which it has been tried. Mangold-wurzel undoubtedly benefits by its application; and one or two cwt. per acre, in inland situations, will benefit other crops as well. Quick-lime slaked with salt water is a powerful manure.

It is hardly consistent with the character of this Cyclopædia that instruction should be given in extreme detail on the source and supply of the manures of the farm, but the conclusion may be named, that on well-managed land, cultivated on the alternate system of cropping, where at least one-half the land grows grain, there will be a supply of from 3 to 4 tons of dung per acre, according to the rotation adopted, and certainly not more than 5 tons, even under good management, and heavy crops. But what is wanted under such a rotation? Suppose it to be a six years course of cropping, namely,—1, wheat; 2, beans; 3, wheat; 4, swedes; 5, barley; 6, clover. There are at any rate two crops to which dressings of farm-yard dung are desirable,—namely, beans and swedes; and in England, the clover, also, either before it has yielded its crop or after it, for the wheat often then receives a dressing. In the former case 100 acres, and in the other 150 acres, on a farm of 300, have to receive a dressing of manure. A quantity equal to 1000 tons is all that can be expected, and the 10 tons of dung, which is all that can be given per acre, according to the one system—the 7 or 8 tons per acre, which is all that it provides in the other case—are a very imperfect dressing indeed. What is wanted, in order to a thoroughly liberal treatment of the land? On 50 acres of clover, 500 tons of yard manure are wanted; on 50 acres of beans, 750 tons of yard manure are wanted, besides at least 7½ tons of guano. Over the 50 acres of turnips we want 750 to 1000 tons of farm-yard dung. These quantities amount to 2000 tons of dung,—a quantity which it is useless to expect, seeing that it is double what good management supplies.

Hence the need of artificial assistance to eke out the means which the domestic supplies provide. Till within the last few years the ordinary plan of doing this was by means of compost heaps, in which, by the aid of a little farm-yard dung as a ferment, materials less liable to decomposition were induced to rot together; in which, too, the waste products of other processes were economised and turned to use. What a number of things may thus be turned to good account is apparent from the mere list of them:—Animal, vegetable, and mineral substances existing upon the farm; roots, hedge clippings, and fallen leaves; couch grass, fern leaves, moss, river and sea weeds, sods and turf from ditches, lanes, and hedge-rows; saw-dust, spent bark, and peat, when properly decomposed. Many of these contain nitrogenous ingredients in larger proportion than the straw of grain, and several of them are equally rich in the mineral constituents of plants. Animal substances, such as carcasses, blood, bones, fat, blubber, waste fish, sprats, and various shell fish, are, in particular places, to be sometimes had abundantly. They all contain nitrogen, and so are capable of forming ammonia in larger quantity than our highly valued farm-yard dung. Mineral substances also are available: earth from hedges, scourings of ditches, banks, ponds, &c., containing a large share of vegetable matter, and road-scrappings are also elements of composts. Many

refuse substances of trade and manufactures are also available in this way: woollen rags, shoddy, soapers' waste, soapers' ley, paper waste, glue refuse, and refuse of salt-works, of starch-works, sugar-works, slaughter-houses, cider-mills, gas-works, &c., may thus all be used. Many of them are not fit for use in their natural state; but in compost with others, and suffered to rot there, they become useful.

Composts, too, are useful as diffusing and diluting stronger applications: guano may thus be economised. They exercise a beneficial influence on fertility, in virtue of their mechanical effects upon the soil. Stiff soils may thus be improved by vegetable composts, and light soils by heavy composts. Lime, of course, is a chief ingredient in composts, and has been already adverted to. Let us, however, call attention to the labour of making and carting bulky and comparatively poor manures, as composts generally are, in order to defend the greater economy as a general rule of purchasing artificial fertilisers, in order to supplement the deficiency of what may be called the natural supply.

What an immense variety of artificials, so-called, which the farmer has now at his command, is apparent from the following list:—

Guano.	Nitrates of soda and potash.
Bones.	Gypsum.
Superphosphate.	Salts of various kinds.
Blood manure.	Soot and charcoal.
Wool manure.	

To guano reference has already been made. [GUANO.] It may be applied to almost every crop with advantage, and it is well to mix it with mould for diluting it, or with common salt for preserving it. M. Barral, a well known French agriculturist, "exposed to the air for fifteen days equal weights of guano, and of guano mixed with half its weight of common salt, and he found that pure guano lost 11.6 per cent. of its nitrogen during that time, while that mixed with salt had lost only 5 per cent." And Mr. Northcote's conclusions are, that "agricultural" salt is an energetic absorbent of ammonia, both on account of its chloride of sodium, and on account of the sulphate of lime which it contains; and that the quantity of lime-salt present especially, most powerfully affects its action in this way. Its agency, however, does not seem to be a very permanent one, though it will collect and retain the ammonia long enough, probably, for agricultural purposes.

When thus mixed with a substance, which at the same time that it fixes more or less the volatile ingredient of guano, does also increase the bulk of the manure, and so enable its more even distribution over the land, it should be applied during, or immediately before the season of most rapid growth; as, for instance, if for grass, just after a mowing, when the young plants, furnished with a full grown apparatus of roots are prepared to make rapid use of whatever food for plants is presented to them. For the same reason too, it is best applied to the wheat crop in spring time over the young plant, rather than before the sowing, whether that is spring or autumn. In that case, some 3 or 4 cwt. per acre of the manure properly prepared is sown broad-cast, and hoed or harrowed in, or if, during wet weather, left without a harrowing. For green crops again, as swedes or mangold-wurzel, it is more commonly sown broad-cast over the raised drills, between which, the farm-manure is placed, and then covered by the same splitting of the drills which covers the manure. Or if the seed is sown upon the flat, the guano is mixed with a large quantity of ashes, and either sown broad-cast previous to the harrowing which precedes the sowing machine, or it is drilled under the seed by the same machine—a separate set of weighted coulters being used for its conveyance—the effect being, that the manure is covered by the earth before the seed is deposited above it.

Of all the other artificial fertilisers now available in English agriculture, that which most directly comes in competition with guano is the nitrate of soda, of which it is probable that large supplies may become available, especially from Peru. The nitrates of potash and soda are applied at the rate of about 1 cwt. per acre, and especially on poor lands they wonderfully increase luxuriance of growth in corn crops, and the consequent yield of corn per acre. In several instances 1 cwt. per acre has produced an increase of 12 bushels per acre in the wheat crop, and of 4 or 5 sacks in the oat crop, and though it is especially influential in the case of poor lands, yet that it is also of great service on fertile soils well-managed, is plain from the following statement by Mr. Hope, of Fenton Barns, Haddington:—

He says in a letter to Mr. Pusey, "I have only applied nitrate for two years to wheat, and that after seeing the account of your own experiment in Mr. Caird's 'English Agriculture.' In April, 1852, I top-dressed wheat after potatoes; the soil a dry gravelly loam. At the time the wheat was not very promising in appearance, I sowed on part 1 cwt. nitrate mixed with 1 cwt. salt per imperial acre; on another portion 3 cwt. Peruvian guano was applied, and a part got nothing. The nitrate of soda soon took the lead, and kept it. A portion of each was threshed separately, when they were found to yield as follows, viz:—

PER IMPERIAL ACRE.			
	Straw.	Wheat.	
1 cwt. nitrate of soda	37½ cwt.	53	bushels.
3 cwt. guano	36 "	49	"
Nothing	33 "	39	"

"In 1853 I tried the same thing on wheat after beans; I never, however, could detect any difference with the eye, except where the crop got nothing, though in the former year the difference between the two manures could be seen at a glance; and having cut the crop with a reaping machine, which rather intermixed the lots, I was prevented threshing them separately. I have bought 5 tons of nitrate for next year and mean to apply a portion to potatoes."

The only reason why nitrate of soda is preferred to nitrate of potash depends upon the greater cost of the latter. The proper time for sowing either is during the period of rapid growth; they, like all soluble manures, are immediately spread throughout the soil by the showers, and of course are liable to waste unless the plant to which they are applied be ready to use them at once. Both of these salts are liable to adulteration, and common salt is the chief substance used for this purpose; its presence is detected on throwing any of it on some hot coals by the crepitating sound which follows. Pure nitre burns the coal up without any of these little explosions.

We come now to the use of bones as a manure. Raw bones contain perhaps half their weight of phosphate of lime; when burnt they contain perhaps 60 or 65 per cent. of phosphate of lime. It is chiefly for this phosphate that the bone manure is valuable, and as in addition to the greater quantities of phosphate which burnt bones contain, they are also superior as regards the facility with which they can be decomposed, burnt bones are more valuable agriculturally than raw ones. This phosphate exists in the mineral world both as fossils and simply in the mineral form; some of the fossils contain half their weight of phosphate of lime; and apatite, a mineral phosphate imported from Norway and America, contains upwards of 90 per cent. of phosphate of lime. It is, however, in its natural state almost valueless as a manure, owing to its insolubility; and as the agricultural value of bones can be greatly increased by increasing their solubility, so whatever value this mineral phosphate possesses is conferred upon it by the same process.

This process consists in the adoption of means which shall have the effect of reducing the material to a fine state of division. When the phosphate of lime is acted on by sulphuric acid one half the lime is taken forms it by the acid, and so sulphate of lime or gypsum is produced, the other half of the lime in combination with all the phosphoric acid forms what is called super-phosphate, which is characterised by its solubility in water; and although when it becomes mixed with the earth when put on the land, this extra quantity of acid becomes neutralised by the lime or the alumina of the soil, yet having been once decomposed the bone earth retains so exceedingly finely divided a state that rain is able to act upon it as a solvent much more powerfully. The reason why bone-dust is more powerful as a manure than the original bones is, that its finer division gives a larger surface for rain water to act upon, and wash off a portion of its substance as food for plants. Ground and fermented bones are thus more immediate in their action. For further remarks on the use of bones and guano we refer to articles on those subjects. It is to them that we mainly look in this country for the means of supplementing the natural supply of manure on the farm.

It is not worth while going into any detail regarding the particular fitness of other special manures. In practice no reader is likely to go into the manure market for sulphate of magnesia and soda, nor even for silicates of potash and of soda; though these are said to be directly useful in strengthening straw. If the farmer can get a supply of guano, bone dust, superphosphate, and nitrate of soda, to supplement farmyard dung, he is not likely to go further.

As to the value of special mixtures of different salts on manure, certainly the fancy for that kind of thing ran wild some years ago, but the relative values of manures are becoming now better understood. It is, however, right that we should say a word on soot as a manure. It is used everywhere with good effect in virtue of the gypsum which it contains, and in virtue of the small quantity of ammoniacal salt which it retains as driven off from the coal. Thirty bushels per acre are a common dressing for grass; and for potatoes it has been long known as a useful manure.

Leaving now the subject of auxiliary manures—which has latterly become one of the most important in the whole range of English agriculture—we recur once more in conclusion to the ordinary farm practice connected with the annual replenishment of the soil. Farm buildings should be so made as to remove all the water which falls upon the roofs, that it may not dilute the manure made in the yards. Their yards if any are open should be small and partly covered. Arrangements for feeding in boxes where all the excrement is absorbed by the litter are to be preferred; and where yard-manure is made, or stall-fed cattle have to be daily cleaned out, the manure thus daily made should be daily removed to heaps made on Mr. Lawrence's plan, to which reference has already been made.

One word further may be allowed on the practice of folding sheep on land, and of top dressing clover and grass lands; the policy of that practice has been remarkably justified by the researches of Dr. Völcker, to which allusion has been made. Hitherto the wastefulness of top dressing has been admitted universally, and the practice has been regarded as one of the unfortunate circumstances connected with the plant so treated, which could not be avoided. Both top dressing and folding, however, which latter has all along been distinguished by the

fertility it conferred, may be now regarded as practices which, if rightly performed, are not more wasteful than other modes of applying manure. It is becoming more and more the practice in England to apply the bulk of the farm-manure in this way. Clover, either immediately after the barley harvest, or during that autumn, receives a dressing of 10 to 15 tons of farm-yard dung, which as it has been made during the previous spring, is generally in a very well rotted state; or the same clover receives a heavy dressing in the subsequent autumn, previous to being ploughed up for wheat. The former is considered the best plan, at least as regards that portion of the clover which is to be mown in the following year. The turnip crop is thus being left more and more dependent on the use of artificial manure—a half-dressing of dung and a good dressing of superphosphate of lime is found equal in effect to the best whole dressing of dung which under other management the farm could afford.

One word on the practice of folding sheep on land in the case of light soils. It will no doubt be a permanent practice. Probably a larger portion however of the green crop break is being harvested and carried home to yards, for fattening stock to help convert the straw into dung, and to help, along with the consumption of clover, hay, and cake and corn, to make much better dung than has hitherto in general been made. Probably on a light-land farm in Norfolk, one-third of the turnip-crop will be carried home, leaving two-thirds on the land for sheep. On the best managed lands there, every sheep will consume 1 cwt. of cake or corn, in addition to the 12th part of an acre of swedes, and if in doing that it increases 10 or 12 pounds a quarter, as it probably may, it will do little more than simply return in its excrements all the green food which it has consumed. That turnip crop had built up its bulky structure at the expense of the deeper as well as of the shallower soil (for we have traced the roots of turnips 4 feet downwards), and largely also out of the material which it has gathered from the air; and by means of the sheep this large quantity of plant food, gathered from subsoil and from air, is all accumulated in the upper soil, greatly of course to its advantage, and greatly to the advantage of the subsequent wheat crop, and of such plants as, like it, may be more exclusively dependent than the turnip is upon the material which the surface soil contains. The material thus lodged upon the soil is in a form in which it is more liable to putrefaction and waste than it was: but air washes these fugitive ingredients into the land, and the plough soon covers all up; and when the mechanical structure of the land is such as to benefit by the treading of the animals thus fed, there is no operation in the whole range of farm practice which at once adds such an increased fertility to the soil.

MANURING, in horticulture, requires to be considered in a somewhat different light from that process as applied to agricultural purposes. This is necessary because of the variety of plants, possessing different constitutional habits, to which the gardener is required to turn his attention, and also because of the different results which are expected in horticulture and agriculture. In preparing the present article, the writer has confined himself to simple practical facts, and has adverted only occasionally to chemical explanations.

The gardener is called upon to cultivate species from almost every kind of soil on the surface of the globe, intermediate between the shifting sands of the desert and the most fertile alluvial land continually enriched by the decay of vegetable and animal substances. It is therefore obvious that considerable caution is requisite in applying manure, and in determining the quantity or quality suited to the respective constitutions of the various subjects which the horticulturist takes under his care. Thus, although many plants can scarcely receive too much manure, others, such as the resinous trees, may be actually killed by it.

The kind of manure chiefly used, and frequently the only kind procurable by the gardener, is that derived from the farm-yard, consisting chiefly of the dung of horses or of horned cattle, more or less mixed with litter. Formerly it was very generally the custom to take advantage of the heat resulting from the fermentation of such dung in hot-bed forcing, and there are still some objects for which this kind is found preferable [HOT-BED]; but since the hot-water system of heating has received so many improvements, the continued fermentation and consequent degree of decomposition which dung undergoes in hot-beds is rendered a less important means of obtaining artificial warmth, and consequently it becomes the more important to inquire whether manure is most beneficially applied in a state of decomposition, as some have advocated, or in a state as recent as possible, no fermentation being permitted previous to its deposition in the soil.

If dung contains a large proportion of litter, and particularly if the latter be in a dry state, it will be advisable to subject it in nearly all cases to a moderate degree of fermentation, assisted by a sufficient quantity of moisture, in order that the fibre of the straw may be reduced to a state permeable by the spongioles of plants, and either become sufficiently dissolved for affording nourishment itself, or serve in the first instance as an absorbent reservoir for substances of still greater solubility. Where such preparation has not been attended to, litter has been frequently observed, when turned out of the ground after a dry summer, to be still in a dry musty state, having evidently been of little benefit to the crop; and in the case of many plants, which require much manure, litter in this state would actually prove very injurious. But if the dung be what is termed short, containing

little straw, and that well saturated with the liquid proceeds of the stalls, it may be dug in without fermentation for most kitchen-garden crops, provided it is well divided and properly mixed with the soil in digging or trenching in. This is necessary in all cases, but more especially so when the manure is applied fresh; for disease is often induced by the roots entering into masses constituted of particular substances which either wholly or, at all events, too powerfully predominate over the proper nutritive solutions.

But, on the other hand, if the soil is of a wet and stiff nature, then long unrotted dung is most proper, because its straws form so many minute drains, which, to speak technically, keep the ground open; and in such soils, by means of littery manure and drilling, a crop of potatoes, for example, can be raised very superior in quantity and quality to that obtained from the application of rotten dung. In this case the previous reduction of the fibre of the straw is not requisite; for the moisture of such soils is sufficient to effect this by degrees, and whilst the process of growth is going on. The authority of Miller may be adduced on this subject; in his 'Gardener's Dictionary,' he observes, "In very cold moist land, I have frequently seen new horse-dung buried as it came from the stables, and always observed that the crops have succeeded better than where the ground was dressed with very rotten dung."

On the other hand, dung that has been moderately fermented, and frequently turned over, so as to be easily cut with a spade, is the most proper for such trees as require manure, or for slow-growing crops, where the roots have to remain for years in contact with it. With regard to trees and many perennial plants, no more injury would be incurred by using fresh dung instead of rotten, for the first season, or rather whilst vegetation continued active; but after the roots become nearly dormant, canker or disease of some sort is apt to ensue. The roots may have grown luxuriantly during the summer; but when they are arrested by the approach of winter, decomposition will still be going on amongst the materials on which they feed, and these materials may perhaps be chemically changed, before the roots are again called to action.

These remarks relate chiefly to the description of manure which is most generally used. Other substances which are or may be successfully applied to promote the growth of vegetation are exceedingly numerous. [MANURE.]

Animal substances are very powerful manures, and require to be attenuated or diluted before plants can derive nourishment from them, or in fact before either roots or tops can be safely brought within their contact. If the roots of a plant be wholly immersed in oil or in blood, that plant will be destroyed. Blood is one of those liquid manures which is occasionally supplied to plants so situated as to render bulky manure inapplicable; but it should unquestionably be copiously diluted with water, and be allowed to rot in compost. Bones are another form of animal matter much employed, and of considerable energy, especially in calcareous soils, provided they are reduced into small fragments and fermented before being used. Gardeners often use them in that state; and now, as dissolved in sulphuric acid, they are, of course, as available in the garden as in the field.

The liquid portions of excrementitious manure likewise require either to be diluted with water or to receive an admixture of soil before they are brought in contact with the roots of plants. In the case of trees with roots lying deep in the ground, such dilution is not always necessary; but, generally speaking, adherence to the rule is advisable.

Flesh, or the carcases of dead animals, should be chopped up and covered and mixed, with many times their bulk of soil and with some lime. This, when turned over, will still form a very strong manure, and for some plants much too strong; but for such as the vine it will form a valuable compost, particularly if broken bones are added to it.

Manures derived from the vegetable kingdom require little preparation if they consist of succulent plants; their substance is easily soluble, and they may therefore be turned fresh into the soil. The period of their growth when this is most beneficially performed is before they run to seed. Weeds may even be used with great advantage, if properly prepared; but bad consequences may result from their seeds rendering the ground foul, and thus occasioning much expenditure of labour to extirpate them again. Seeds, it is well known, will not germinate without air; but with this, and sufficient heat and moisture, nothing can prevent them from germinating. Therefore if weeds be thrown into a heap and turned, whilst at the same time fermentation is encouraged till the heat is fully equal to that which would naturally cause the germination of the seeds, taking care that the outside be turned into the centre, no danger will arise from using such manure after the process has been continued sufficiently long for the germination of the slowest vegetating seeds which the heap may contain, because under these circumstances the young plants will be continually perishing as the heap is turned over from week to week. There are many aquatic plants that will not grow on dry ground, and a preparation similar to the above is not essential for the purpose of killing their seeds before their application to dry ground, which is not, so to speak, their proper element.

Woody fibre unfermented is useless as a manure; and tanner's spent bark, a substance very absorbent and retentive of moisture, is not

capable of affording nourishment, until the tannin is got rid of by fermentation, when plants, as may be observed in bark-beds, root very readily in tan. Inert peaty matter is a substance of the same kind, and will remain for years exposed to air and water without undergoing change. When peat becomes inert, it is in vain to attempt to grow any sort of plant in it; but nothing is more certain than that if drained of stagnant moisture and mixed with lime and dung, it will become very fertile for most crops. It often happens that peat or *bog-mould*, frequently procured at a great expense for American plants, becomes inert; in such cases, a good result would be obtained by turning out the peat and mixing it up in a heap with a quantity of leaves or fresh litter sufficient to promote a moderate degree of fermentation; then, as in the case of tan, it will afford nourishment, and will, from a state of uselessness, become valuable.

Of mineral manures *lime* is the most useful. It is not recommended for soils that contain a large proportion of soluble vegetable matter; but it produces excellent effects in such as abound in inert vegetable fibre. Gypsum, which is found in the ashes of grasses, proves a manure for lawns.

Common salt is sometimes employed in minute portions; especially in combination with vegetable matter, in the instance of sea-weeds, in which case it is found of good quality for fruit-trees and kitchen-garden crops; but vegetable life is certainly destroyed by it, if applied in any considerable quantity. Exceptions may be noticed in the case of marine plants; the samphire for example, requires it when cultivated in inland districts; and this is also true of the vegetable inhabitants of the great salt plains of Asia. Wood-ashes, which consist principally of vegetable alkali united to carbonic acid, are a good manure, but of short duration, and they leave peaty soil in a worse state than before their application. The application of dung and lime, of composts of clay, marl, scorings of ditches, &c., would render peat *permanently* fertile, more especially when draining is judiciously attended to.

MANUSCRIPTS. [PALÆOGRAPHY.]

MAP (Latin, *mappa*, a napkin; French, *mappemonde*, a map of the world). A map is a representation of the surface of a sphere, or a portion of a sphere, on a plane. The name, however, is commonly applied to those plane drawings which represent the form, extent, position, and other particulars of the various countries of the earth.

Maps, or delineations resembling them, we may reasonably conclude were coeval with the earliest geographic knowledge; but it is not possible to fix the time of the first attempts to construct maps. The geographical knowledge of the Greeks, as exhibited in the Homeric poems, comprehended only a small part of Europe, Asia, and Africa, and there is not the slightest allusion in them to any mode of delineating or representing the surface of a country. In their maritime adventures the Greeks are said to have been assisted by the nautical maps of the Phœnicians; but however this may be, we have no account of anything deserving the name of maps before those of Anaximander the Milesian, who is alleged to have been the first to construct a map of the world. Itinerary maps of the places of encampment were almost indispensable to the commanders of armies; Diogenetus and Beton are mentioned (Pliny, 'Nat. Hist.' vi., 17) as the surveyors of the marches of Alexander, who was very careful in examining the measures of his surveyors, and in obtaining his descriptions from the most skilful persons. The science of geography made rapid advances under Eratosthenes [ERATOSTHENES, in BIOG. DIV.; 'GEOGRAPHY'], who had the great merit of reducing geography to a regular system, and of founding it upon solid principles. He introduced into his map a regular parallel of latitude, which he accomplished by tracing a line over certain places whose longest day was observed to be of the same length. This parallel extended from the Strait of Gibraltar to the mountains of India, passing through the island of Rhodes; and from its central position with respect to the principal ancient nations, it became a standard of reference in the maps of this period. Succeeding geographers made many attempts to determine the longitude of places by measurements of this line, but with no great success. Eratosthenes, in addition to the parallel above mentioned and other parallels, undertook to draw a meridian from Meroe through Syene to Alexandria ('Strabo,' ii. 114), and also to determine the earth's circumference by the actual measurement of a portion of one of its great circles. These discoveries and improvements very materially affected the dimensions of all the ancient maps; and from this time the connection between astronomy and geography was so far established as to ensure an advantage to the latter by every advance of the former. This was eminently the case in the discoveries of Hipparchus, who fixed the construction of maps on a mathematical basis, and enabled the geographer to lay down his latitudes and longitudes upon certain principles.

To Strabo we are chiefly indebted for our information respecting the state of geography in the Augustan age. But the extent of the earth's surface known to this writer does not very much exceed that which was known to Herodotus four centuries earlier. His map of the world exhibits some remarkable errors. He supposed the Pyrenees to run north and south; cuts off the projecting province of Brittany from France, places Ireland not to the west but to the north of Britain, and makes the Caspian communicate with the northern ocean though Herodotus had accurately described it as a lake.

The Roman Itineraries show that their surveys were made with considerable care, although there are no traces of mathematical geography in those which have been handed down to us, the chief object in view being the clear direction of the march of their armies. All the provinces of the Roman empire had been surveyed when Ptolemy composed his system of geography, which has happily been preserved to us. It is not so much to his more perfect acquaintance with the earth that Ptolemy owes his reputation as a geographer, as to his giving solidity and unity to the science by fixing its unconnected details on a mathematical basis and carrying into full practice and to greater perfection the system of latitudes and longitudes of Hipparchus, whose invention had been much neglected for upwards of 250 years.

It seems not improbable that the maps found in the MSS. of Ptolemy are really copies of, or derived from, original maps constructed by him or under his care. [AGATHODÆMON, in BIOG. DIV.]

The geography of the Arabians is but imperfectly known. Their most eminent geographer Edrisi or Eldrisi, who lived about the middle of the 12th century, divided the world into seven climates from the equator northward, and each climate was again divided into eleven equal parts, from the western coast of Africa to the eastern coast of Asia, the inconvenience of which arrangement is very obvious.

Towards the middle of the 17th century several astronomers undertook to observe eclipses of the moon, with a view of correcting the errors in the longitude of places. These observations, however, were so discordant as to lead to no satisfactory result. Galileo, by the discovery of the eclipses of the satellites of Jupiter, introduced a more certain method, which was rendered available by means of the simultaneous observations of Picard and Cassini at the observatories of Uraniburg and Paris.

Picard and De Lahire were then immediately employed in correcting the map of France, and from this period our maps have rapidly improved. The great perfection to which timekeepers have been brought, and the obvious application of these machines to the determination of the longitude, have greatly contributed to their accuracy. But notwithstanding the advanced state of our astronomical and geographical knowledge, and the science and skill displayed in our great national and other surveys, we may, with Dr. Blair, regard maps as works in progress—always unfinished, and still waiting the corrections to be supplied by the science and enterprise of succeeding ages.

Having thus briefly sketched the progress of map-making, we proceed to give a general outline of the application and construction of maps.

On the Nature and Construction of Maps.—Maps, being plane representations of the surface of a sphere, may be obviously applied to various purposes; hence we not only have terrestrial maps to represent the surface of the earth, but celestial or astronomical maps to represent the sphere of the heavens; and these general distinctions have again their subdivisions.

There are two kinds of terrestrial maps—geographic or land maps, and hydrographic or sea maps: we shall confine our attention principally to the former; the latter, which are usually called charts, having been already described. [CHART.]

Geographic maps, as already noticed, are those which represent the forms and dimensions of the several parts of the earth, with their relative situations and the positions of the cities, mountains, rivers, &c., comprised within their limits. They may comprehend the whole earth, or one of its larger divisions, or a single district, and are called maps of the world, general maps, or particular maps accordingly. If they give the nature of the ground, the roads, buildings, &c., in detail, they become topographic maps, which, necessarily embracing a very small extent of country, are not usually referred to any spherical projection, but are represented as geometric planes, the objects in them occupying the positions severally assigned to them by the trigonometrical operations of the survey. The same distinction is made in charts of small bays and harbours. In either of these cases they are called plans.

When maps of the earth are made to illustrate any of the sciences, they are distinguished from geographic maps, properly so called, and bear their own peculiar names, as geological, or mineralogical, or botanical maps. A collection of such maps is called a physical atlas: such are the admirable atlases published by Berghaus, Johnston, and Petermann, in which the results of the investigations in geology, geography, hydrography, magnetism, meteorology, &c., are presented distinctly to the eye.

Of late years the leading governments of Europe have published maps showing, on a comparatively large scale, the results of elaborate trigonometrical surveys of the several countries: the maps of Austria and France are beautiful examples. In England, the results of the Ordnance Survey of a large portion of Great Britain and Ireland have been published in a series of admirable maps, at an extremely moderate price. The chief drawback is that, in the long intervals between the publication of the different portions, material alterations are taking place with extraordinary rapidity. New railways are made; old roads are stopped up, and new ones opened; new towns spring up round railway stations, and villages become towns. Perhaps no mode of publication could be adopted to keep pace with these changes; and

the plates are amended by laying down the new lines of railway whenever they are reprinted.

On some of these government and other large maps of recent production contour-lines have been adopted in the place of shading, to indicate the heights of mountains. A good example of the application of contour-lines is afforded by the large-scale Ordnance maps of Ireland. On the other hand, the Ordnance maps of Wales, and generally the later inch-to-the-mile maps of the British survey, afford very beautiful illustrations of the plan of graduated shading to a carefully considered scale for orographical delineations. But much yet remains to be accomplished, at least in ordinary maps, for the delineation of the true forms of mountains, the varying features of valleys, and, in fact, the general configuration of the surface of a country.

Of late, also, relief- or model-maps have been published, which show the orographical and other physical features of countries and districts, by producing the various elevations in bold relief of proportionate heights, by means of pressure upon softened and specially prepared paper. Some beautiful specimens have been produced; but, when executed with accuracy, the process is too costly to come into general use.

From the spherical form of the earth, it is obvious that the divisions and varieties of its surface may be most simply and most accurately represented by means of a globe; and, in order to obtain a correct notion of its general geographic features, there is no mode of representation so satisfactory. Large globes, however, are expensive and inconvenient instruments, and small ones, by not admitting sufficient detail, are for most geographic purposes entirely useless. Hence we see the eminent utility of maps, notwithstanding the imperfections which necessarily accompany such a mode of representation; for a spherical surface can by no contrivance be extended into a plane without a distortion of some of its parts.

The methods adopted in the construction of maps are as various as the taste and judgment of geographers themselves, but they may all be referred to two principles—namely, *projection* and *development*.

By *projection* is meant the representation of the surface of a sphere on a plane, according to the laws of perspective. By *development* is to be understood the unfolding or spreading out of the spherical surface on a plane. This, however, first supposes the sphere to be converted into a cone or a cylinder,—these being the forms, portions of which most resemble portions of a sphere, and which at the same time are susceptible of the required development.

We shall notice these two principles very briefly, as their mathematical investigation more properly belongs to the article PROJECTION.

There are four methods of spheric projection in general use,—the *gnomonic* or *central*, the *orthographic*, the *stereographic*, and the *globular*,—distinguished from each other by the different positions of the projecting point in which the eye is supposed to be placed.

The *gnomonic* or *central projection* supposes the eye to be placed in the centre of the sphere, and that the various objects to be delineated are transferred from the sphere to a plane, which is a tangent to its surface. The entire hemisphere can never be represented by this projection, since the circumference which terminates it is on a level with the eye, and is therefore parallel to the plane of projection. This method is chiefly used in dialling, but may be advantageously applied

to maps of a limited extent, more especially if they are maps of the polar regions of the globe. In this case the meridians will be straight lines radiating from the centre, and the parallels of latitude concentric circles, whose distances from the centre will respectively be equal to the cotangents of their latitudes.

In the other cases of this projection, where the perspective plane is parallel to the horizon, or to any meridian, the construction is rendered troublesome on account of the parallels of latitude becoming curves of difficult delineation: these cases therefore are seldom brought into use.

Orthographic Projection.—In this projection the eye is supposed to be at an infinite distance, so that the visual rays leave the sphere in parallel lines. The perspective plane on which a hemisphere is supposed to be delineated is the plane of that diameter which is perpendicular to the visual rays: hence every point of the hemisphere is transferred to this plane by perpendiculars let fall upon it. It will be immediately seen from the figure, that the representation will decrease

in accuracy with the increase of distance from the centre; the parts near the circumference being much foreshortened and distorted.

In a *polar map* of this projection, the meridians, as in the gnomonic maps, will be radii, and the parallels concentric circles; these circles, however, will have their distance from the centre equal to the cosines, and not to the cotangents of their respective latitudes.

In an *equatorial map*, or one in which the equatorial regions of the globe are made to occupy the centre of the map, the plane of projection coincides with the plane of one of the meridians. In this case the latitude circles will be projected in straight lines parallel to the equator, which is also a straight line, and will vary in distance from it according to the sines of their respective latitudes. The meridians will be portions of ellipses intersecting the equator in points similar in position to the intersecting points of the parallels on the polar diameter, and having their transverse axes coincident with this diameter and equal to it.

Stereographic Projection.—In this projection the eye is supposed to be placed at the surface of the sphere, and to view the concave of the opposite hemisphere through the plane of that circle, in the pole of which the eye is placed.

If E be the eye, and A, G, C the hemisphere to be represented, A, B, C, D will be the plane of projection; and the position on this plane of any point of the spherical surface will be indicated by a line drawn from that point through the plane to the eye. Thus the points K, L, M, N on the sphere will be transferred to the plane at k, l, m, n.

The advantages offered by this method of projection have brought it more into use than the methods before mentioned. It is especially calculated for maps of the world, as usually made in two hemispheres, from the circumstance of the representation being less distorted, and also on account of the meridians and parallels intersecting each other at right angles, as they do on the globe. Its construction also is less difficult than others, since all the great circles of the sphere are either circles or straight lines in the projection. The meridian of 20° W. is the one usually selected by English geographers for the plane of projection in these maps of the world, because this meridian passes very nearly between the eastern and western continents, which therefore occupy their respective hemispheres.

Globular Projection.—This projection, which is a modification of the Stereographic, was invented by the astronomer De Lahire, who supposed the eye to be placed at a distance from the sphere equal to the sine of 45°; that is, if the diameter of the sphere be equal to 200, the distance of the eye from the nearest point of the circumference would be 70 $\frac{7}{10}$. Some further modification was subsequently deemed desirable, in order that the meridians might intersect the equator at equal distances. This condition is very nearly fulfilled when the distance of the eye is 59 $\frac{1}{2}$, the diameter being 200 as before.

This projection is also much used in maps of the world, but to simplify their construction, the meridians and parallels are projected

into circular instead of elliptical arcs, the deviation from the strict law of the projection being too slight to affect the practical utility of the map.

Of Projection by Development.

The developments to be mentioned are two—the *Conical* and *Cylindrical*.

Conical Projection.—In this projection the sphere is supposed to be circumscribed by a cone, which touches the sphere at the circle

intended to represent the middle parallel of the map. If the points on the sphere be now projected on the cone by lines drawn from the centre, it is clear that in a zone extending but a short distance on each side the middle parallel, as the zone $a a' b b'$, the points on the cone would very nearly coincide in position with the corresponding points on the sphere. All the delineations having been thus made, the cone is then conceived to be unrolled, or developed on a plane surface.

Should the map be made to extend much above or below the middle parallel, the distant parts will be very much distorted. To remedy the defects of this projection, various modifications have been suggested, among which those of Flamsteed are generally held in the highest estimation. [CONIC PROJECTION.]

Cylindrical Projection.—From what has been said of the cone, it will be easily understood that a cylinder may be applied to the sphere in a similar manner, and that a zone of very limited extent in latitude may, without very material error, be developed on a cylinder. The peculiarity of this method is, that the meridians, as well as the latitude circles, are projected in parallel straight lines; a condition of the map which makes it very applicable to nautical purposes, and on which (partly) is founded the very ingenious method called *Mercator's Projection*, which is now so universally adopted in our charts, and which, in conclusion, we will briefly describe.

Mercator's Projection.—The line on which a ship sails, when directing her course obliquely to the meridian, is on the globe a spiral, since it cuts all the meridians through which it passes at equal angles. This circumstance, combined with others, rendered a map constructed on the principles of the spherical projections very inadequate to the wants of the navigator. Mercator considered, very justly, that mariners do not employ maps to know the true figures of countries, so much as to determine the course they shall steer, and the bearing and distance of those points or places which lie near their track; and this projection is the result of his efforts to secure to the seaman these desirable ends. The merit of this most useful method is thought by many to be more justly due to Wright; for although Mercator published his first chart in 1556, he omitted to declare the principles on which he proceeded, and his degrees of latitude did not preserve a just proportion in their increase towards the poles. Wright, in 1599, corrected these errors, and explained the principles of his improved construction, in which the degrees of latitude on the chart were made to increase towards the poles, in the same ratio as they decrease on the globe; by which means the course which a ship steers by the mariner's compass becomes on the chart a straight line; the various regions of the map, however distorted, preserve their true relative bearing, and the distances between them can be accurately measured.

The use of this projection constitutes the principal difference between the methods of travelling by land and by sea, and perhaps there is no point of navigation on which a person who is neither a seaman nor a mathematician has so little chance of gaining any information from popular works.

We shall suppose the ship a mathematical point in comparison with the earth, and imagine the whole of the latter to be covered by sea. Also let the ship be always sailing before the wind, and no allowance

for leeway or currents be necessary. Throw out also the variation of the compass, that is, suppose the needle always to point due north.

A ship thus circumstanced, if it should continue sailing due north, would in time reach the north pole on a meridian circle of the sphere, on which, if it still kept its course, it would proceed due south, and would at last reach the south pole: such a ship would never change its longitude, except at the moment of passing either pole, when the longitude would alter at once by 180 degrees. If however the vessel sailed continually due east or due west, it would sail upon a small circle of the sphere, being always at the same distance from the pole, and always in the same latitude. In the first case the differences of latitude would give the distances sailed over, at the rate of 60 nautical miles to a degree; in the second case, the differences of longitude, reduced in the same way, and the results multiplied by the cosine of the latitude, would serve the same purpose.

But suppose that the vessel took an intermediate course, say north-east. It would not sail on any circle of the sphere, great or small; for by hypothesis the line of the course is always making an angle of 45 degrees with the meridian; and there is no circle (unless it be the meridian itself, or a parallel of latitude, the equator included) which always makes the same angle with the meridian. Neither could the vessel, keeping such a course, reach the pole; for at the moment when it touches the pole, it is sailing north, whereas by hypothesis it is always sailing north-east. The fact is, that a curve which makes equal angles with all meridians must be a spiral which approaches the pole, encircling it with an infinite number of folds, but never actually reaching it, as in the following diagram, in which the curve 1, c, 2, 3, 4, &c., is that on which a ship would sail from 1 towards the north pole on a course east-north-east, and the curve 1, 5, 6, 7, 8, &c., is that of a course west-south-west towards the south pole. The dotted part of the figure is supposed to be on the other, or the invisible, side of the sphere. A ship sailing from A to B over A C B, keeps one course; but were it to sail over the great circle A D B, the course must be perpetually altering.

The spiral A C B is the only one on which a ship should sail directly from A to B, though there is an infinite number of such curves which pass through both A and B, the reason being, that in every other spiral except A B one or more complete circuits in longitude must be made, and the ship would come again to the meridian passing through A before it reaches B. In the same manner a spiral might be found, passing through A and B, which cuts the meridian of A five hundred times before it passes through B. Of course the shortest course is always preferred; and it is the object of Mercator's projection to lay down such a map of the world, that the straight line joining two points shall be the map of the course which must be followed in order to sail from one to the other in the most direct manner, consistently with always keeping the same point of the compass.

The spirals above described are called *loxodromic spirals*, or *rumb lines*, and under the latter term their mathematical properties are explained. Our present object is to turn the globe into one of Mercator's maps, in a manner which will give the unmathematical reader some idea of its construction. For this purpose suppose the map of the world to be painted on the globe, and let the globe be made of a thin and very elastic material. Let the elasticity of this material increase as we go towards either pole, and so rapidly that it becomes as great as we please at and near the poles. Let the equator E Q be

immoveably connected with the internal centre (supposed fixed) of the globe. If then the north and south poles be pulled away from the equator, the thin membrane of the sphere will be extended; and if the pull be continued until the poles are sufficiently distant, a large portion of the sphere on each side of the equator will assume a cylindrical form, or one nearly cylindrical; and the greater elasticity of the upper parts will cause the small folds of the different spirals to be much more extended than the larger ones, so as to become equal to them. Let the mathematical hypothesis implied in the preceding be carried to its extreme limit, that is, let the poles be pulled to an infi-

nite distance; and let the law of the elasticity be such, that the several loxodromic spirals shall have precisely similar successive folds on the resulting cylinder, that is, let them take a regular screw-like form. The meridians will then all become straight lines parallel to one another; and if the membrane be then fixed in its cylindrical shape, that is, if it lose its elasticity, and if one of the meridians be slit all the way down, and the cylinder unrolled into a plane, we shall have before us Mercator's projection, as shown in the following diagram. The degrees of longitude remain everywhere the same, those of latitude increase sensibly. The map goes up to 80° of latitude, and any part of

the remaining 10° might be drawn; but no space would be sufficient for the whole of the remainder. Any two points A and B, being given, the line AB joining them points out, on the supposition that all the meridians look towards the north, the most direct course on which a ship can sail from one to the other: if a compass were placed at A, then AB would show, AK being the north direction, the point of the compass on which to steer. Again, from C to D the most direct course is on the dark line CD; but CE, ED, is another way of coming to the same point. It must be remembered that the extreme lines on the right and left represent the same meridian, as they coincided before the cylinder was divided for the purpose of being unrolled.

It thus appears that we have a map on which the sailing course between any two places is found by simply drawing a right line. Another advantage, depending upon the nature of the rhumb line however, and not on the projection, is the simplicity of the rule by which the distance sailed can be determined. This is pointed out in RHUMB-LINE.

The preceding is Mercator's projection of the whole 360 degrees of longitude up to 80 degrees of latitude. A chart, as in other cases, is a part of the projection, enlarged to a convenient size.

MAPLE: ECONOMICAL USES. The maple is a very useful tree for industrial purposes, especially in America. Of the sugar-maple it is calculated that there are ten millions of acres in the states of New York and Pennsylvania alone. The wood, when cut, is white; but after being wrought and exposed some time to the light, it assumes a roseate tint; its grain is fine and close, and when polished it presents a silky lustre. It is used in many of the states as a substitute for beech, birch, and elm; it is employed by wheelwrights for axletrees and spokes; it is made into Windsor chairs; it forms the keels and bottoms of many ships built in Maine; and it constitutes the framework of whole villages of timber-houses. The wood of the scarlet or swamp maple is largely used for the frame, nave, and spokes of spinning-wheels; for saddle-trees; for yokes, shovels, and wooden dishes; for bedsteads, nearly equal in richness and lustre to those of the finest mahogany; and especially for Windsor chairs, the manufacture of which is largely carried on at New York and Philadelphia, with maple wood brought down by canal and railway from the forests. The wood has a fine close grain, is easily wrought in the lathe, and acquires by polishing a glossy and silky lustre. Some of the old trees, in which the grain is undulated or curled, have so much strength and toughness added to the natural lightness and beauty, that the wood is eagerly

purchased for making the stocks of rifles and fowling pieces. The wood of the white maple is whiter, softer, and lighter than that of the other species; it is used for making bowls, and in cabinet work, but not so largely as the two kinds just noticed. The wood of the sycamore maple is yellowish, compact, firm, finely-grained, sometimes veined, susceptible of a high polish, and easily worked at the bench or the lathe; it is very much employed in France and Germany by wheelwrights, cabinet-makers, turners, wood carvers, musical instrument makers, toy makers, gunstock makers, and the manufacturers of pestles, rollers, wooden spoons and platters, and numerous other articles: in England and Scotland it is used for many of the above-named purposes, and also for cider presses. Besides these various useful purposes, special examples of the maple are much prized for the beauty of their grain, rendering them well-fitted for surface-veneers for picture frames and cabinet-work. About one specimen in a hundred of the scarlet maple presents a wavy appearance, produced by a serpentine arrangement of the grain, rendering the wood difficult to split and work, but highly beautiful when smoothed and polished. Some specimens of the sugar maple present what is called a *bird's eye* arrangement of the grain; when smoothed and polished, the surface is diversified with roundish spots of peculiar character, reflecting flashes of light in a beautiful way. Mr. Holtzapffel, in an examination to discover the cause of this, found that the stem of the tree, when the bark is stripped off, presents little pits or hollows of irregular form—some as if made with a conical punch; others ill-defined and flattened like the impression from a nail-head. He found that these hollows are caused by internal spines or points in the bark. The layers of the wood being moulded as it were upon these spines, each fibre becomes abruptly curved at these points; insomuch that when cut through by the smoothing-plane, they give, in the tangential slice, the appearance of projections—just as in some rose-engine patterns and medallion-engravings, the closer approximation of the lines at their curvatures causes those parts to be more black or shaded, and produces upon the plain surface the appearances of waves or furrows and ridges.

There are many other economical uses to which the maple is applied. Charcoal made from the sugar-maple wood is much prized in countries where coal-fuel is scarce; while both the plain wood and the charcoal of the sycamore and white species have a high reputation for their heating qualities. The Kalmucks boil the maple-fruit in water, and eat it with milk and butter. The horses and cattle in Nova Scotia browse eagerly upon the leaves of the striped-bark maple. A

coloured liquid, obtained by boiling the cellular matter of the inner bark, is used in America for black-dyeing. Potash is made extensively in the same region from the ashes of the burnt roots; and sugar is largely prepared from the sap, especially of the variety known as the sugar maple.

MARASMUS (emaciation) is a term often used by the older medical writers to designate those cases in which no particular cause for the atrophy of the body was discovered. It is now very rarely employed, since the condition which was thus named is known to be the result of various local diseases, by which the complete nutrition of the body is prevented, or by which a quantity of its material is constantly abstracted; as disease of the mesenteric glands, pulmonary consumption, diabetes, &c.

MARCH, the third month of the year according to modern computation, containing thirty-one days. The Roman year originally began with March, and was in fact so considered in England before the alteration of the style in 1752, the legal year commencing on the 25th of March. Our Anglo-Saxon ancestors called it most commonly *Hlyd monath*, loud or stormy month; and sometimes *Hraed* or *Rhæd monath*, which some interpret Rheda's, others *Rhede* or *Rethe*, the rugged or rough month. The name of the month is said to be derived from that of Mars, the god of war.

Before 1564 the computation of the French year began from Easter, so that occasionally the same year might comprehend two months of March, *Mars avant*, and *Mars après*. If Easter occurred in March itself, the month began in one year and ended in another. The change of computation from Easter to the first of January, in that country, was directed by an edict of Charles IX.

There is an old proverb, mentioned by various writers, which represents March as borrowing certain days from April. These are called, by the rustics in many parts both of England and Scotland, the *Borrowed Days*. They are particularly noticed in the poem called 'The Complaynt of Scotland':

"March said to Aperill,
I see three hogs upon a hill;
But lend your three first days to me,
And I'll be bound to gar them die.
The first it shall be wind and weet,
The next it shall be snaw and sleet,
The third it shall be sic a freeze,
Sall gar the birds stick to the trees.
But when the borrowed days were gane,
The three silly hogs came hirplin hame."

Dr. Jamieson, in his 'Etymological Dictionary,' says, 'These days being generally stormy, our forefathers have endeavoured to account for this circumstance by pretending that March borrowed them from April, that he might extend his power so much longer. . . . Those,' he adds, "who are much addicted to superstition, will neither borrow nor lend on any of these days. If any one would propose to borrow of them, they would consider it as an evidence that the person wished to employ the article borrowed for the purposes of witchcraft against the lenders."

Ray, in his Collection, has a different proverb relating to this month, namely, that "A bushel of March dust is worth a king's ransom;" thereby expressing the importance of dry or dusty weather at this particular season of the year, in an agricultural point of view.

MARCH, in music, is, properly speaking, an air in duple time, played by martial instruments—that is, by inflatable and pulsatile instruments—to mark the steps of the infantry, as well as to amuse and cheer troops of all kinds. It however has long since gained admission wherever music is heard, and consequently is written for every kind of musical instrument. Hence some of the most striking compositions by the greatest masters; as, for instance, the marches in Handel's oratorios; the religious marches ('Marches religieuses') in Gluck's 'Alceste' and Mozart's 'Zauberflöte'; the two funeral marches ('Marsie funebri') of Beethoven; the 'Wedding March' of Mendelssohn, &c.

The true March is always written in common time, or in what is called a compound of that measure, and begins on a broken part of the bar, with an odd crotchet or a quaver. It is slow for grand or parade occasions, quick for ordinary marching. We are told by Rousseau, that Marshal Saxe used the march also for the purpose of accelerating or retarding the pace of his troops in battle. In his days there was more form, more ceremony used; something like etiquette was kept up in fighting; we doubt whether the movements of the battalions in the fields of Austerlitz and Waterloo were performed to musical movements, or even to the simple beat of drums.

MARCHES, THE. The *mark*, Anglo-Saxon *meape*, is a word common to almost all the languages of Teutonic origin. It was the first general division of landed property, and denoted in a specific and peculiar sense those important *marks* by which the boundaries of wide domains were indicated, within which individual or private possessions were contained, the mark being held in common, and in this sense it is found in Anglo-Saxon writings. Hence the word *the marches*, that is, the country lying near and about the *marks* which indicated the limits of two kingdoms, dukedoms, or other extensive jurisdictions.

In Germany, the *mark* gave one of the titles of honour, the *markgraf* (*margrave*), or lord of the marches. (Dönniges, 'Deutsches

Staatrecht.') Our own *marquess* is of the same origin, though it does not appear that the few persons who in early times (there was no English *marquess* before the reign of Richard II.) bore this title had any particular connection with the marches.

Great part of England being bounded by the sea, there could be but little march-land. But on the side toward Wales, and in the north where England abuts upon Scotland, there was march-land; and when we speak of the marches, the land near the borders of the two countries is what is meant.

Harold was lord of the marches against the Welsh, but after they were conquered by Edward I., we hear little in history of the marches of Wales. But the term continued in use long afterwards; and the family of Mortimer, whose chief residence was at Wigmore Castle in Herefordshire, had the chief management of the affairs of the Welsh marches, and bore the title of Earl of March. Edward IV., their lineal descendant and heir-general, was called Earl of March while his father was the Duke of York. The title is yet preserved in the family of the Duke of Richmond.

But Scotland remaining a distinct sovereignty for several centuries after the subjugation of Wales, the marches towards that country are frequently mentioned in history. The maintenance of authority in those regions was an object of great importance; and for this purpose the marches towards Scotland were divided into two portions, the western and the middle marches, each of which had courts peculiar to itself, and a kind of president or governor, who was called the warden.

MARCHESVAN, מַרְחֶשְׁוֹן, commonly called Chesvan by the Jews, is the second month of the Jewish year, and it coincides with our October or November, according to the variations of length required to make each month commence with the appearance of the new moon. In the present year (1860) it begins on the 17th of October. The origin of the name is uncertain; the Jews naturally look for it in the Hebrew root, מַרַחֵשׁ, to "boil up," or "pour forth." Benfey quotes Hyde, who proposes with more probability the Persian *khezân*, the autumn. We find the name *Markazana* on the monument of Darius at Behistun, but the season in which this month occurred is at present unknown. The word is not found in the Bible, but it was known to Josephus, who writes it *Μαρσούαν*, or *Μαρσούαρν*, Antiq. l. i. c. 3, § 3. The Syrian months named Tisrin, which occupy the same period of the year, will account for the names of *Θοριμ* and *Θισριμ* in the calendars of Heliopolis (Balbek). This month has either twenty-nine or thirty days, a variation which is applicable to the following month Chisleu also. In ordinary years Marchesvan has twenty-nine days and Chisleu thirty; when an additional day is required the two months have thirty days each; when it is necessary to have a short year both months have twenty-nine days. This variation is required for the purpose of applying a rule by which the month of Nisan could not begin on either Monday, Wednesday, or Friday; nor Tisri on Sunday, Wednesday, or Friday. No fasts or festivals of general observance occur in this month, though some mention is made of a fast on the 6th, in commemoration of the blinding of Zedekiah by order of Nebuchadnezzar (2 Kings, xxv. 7); and persons who have committed any excess on the Feast of Tabernacles in the preceding month may feel bound to a fast in Marchesvan.

MARCIONITES, a religious sect of the 2nd and 3rd centuries of our æra, so called from their teacher Marcion, a native of Sinope and a priest, who adopted the old Oriental belief, in which he had been preceded by Cerdo at Rome, of two independent, eternal, co-existing principles, one evil and the other good, introducing also a third intermediate being neither perfectly good nor perfectly evil, the creator of the inferior world and the legislator of the Jewish people. He endeavoured to apply this doctrine to Christianity, asserting that our souls are emanations of this third principle. The Jews were subject to this being, while all those nations who worshipped a variety of deities were subject to the evil principle. But the good principle, in order to dissipate these delusions, sent Jesus Christ, a pure emanation of itself, giving him a corporeal appearance and semblance of bodily form, in order to remind men of their intellectual nature, and that they cannot expect to find happiness until they are reunited to the principle of good from which they are derived. Marcion and his disciples condemned all pleasures which are not spiritual; they taught that it was necessary to combat every impulse that attaches us to the visible world; they condemned marriage, and some of them even regretted the necessity of eating of the fruits of the earth, which they believed to have been created by the evil principle. The Marcionites spread far in the East, and especially in Persia. The chief opponent of Marcion was Tertullianus, who wrote a book to refute his doctrines.

(Tertullianus, *Adversus Marcionem*; Mosheim's *Ecclesiastical History*, cent. ii., part ii.; Neander, *Church History*, vol. ii.; Beausobre, *Hist. de Manich.* l. iv., ch. 5, &c.)

MARGARAMIDE. When ammoniacal soap, prepared either from animal fat or olive oil, is treated with boiling water, the soap diffuses through it without being dissolved; on cooling the greater part solidifies on the surface, and this, if dissolved in boiling alcohol, deposits on cooling a substance which, when purified, has the following properties: it is white, crystalline, perfectly neutral, insoluble in water, very soluble in alcohol and ether, especially when hot. It melts at about 140° Fahr., and it burns with a sooty flame.

The solutions of potash and soda decompose it, when concentrated and boiling, ammonia being expelled and soap formed. Acids act upon it only when somewhat concentrated, and more readily when hot than cold. Its formula is $C_{34}H_{35}NO_2$. It is equivalent to margarate of ammonia less 1 equivalent of water; but as margaric acid is probably a mixture of palmitic and stearic acids, the existence of this body as an individual compound must be regarded as more than problematical. [MARGARIC ACID.]

MARGARATES. [MARGARIC ACID.]

MARGARIC ACID ($C_{34}H_{35}O_2$, HO), a fatty acid, so called by Chevreul, who discovered it, from "margarites" (μαργαρίτης), a pearl, on account of its peculiar lustre. It is prepared from soap made with olive-oil and potash; this is to be perfectly dried, and then macerated for twenty-four hours in twice its weight of cold alcohol. The oleate of potash, which the soap also contains, is dissolved by the alcohol, while the margarate of potash remains unacted upon; this is to be well washed with cold alcohol, and then dissolved in 200 parts of boiling alcohol: on cooling, the margarate of potash crystallises; and as it contains a little oleate, it is to be crystallised a second time: it is then to be decomposed, and the margaric acid precipitated by the addition of hydrochloric acid.

The properties of this acid are, that on cooling, after fusion, it crystallises in pearly needles; it is insoluble in water, and hence its precipitation from its compounds and solution by the stronger acids. It has an acid reaction; and its salts, except those of the alkalies, are very sparingly soluble in water. Its saline compounds are termed margarates.

The recent researches of Heintz seem to show that this acid is nothing more than a mixture of palmitic and stearic acids. [PALMITIC ACID; STEARIC ACID.]

MARGARIN ($C_{103}H_{101}O_{12}$), Trimargarin, Margarate of Glycerin. A peculiar fatty matter contained in vegetable oils, and also in animal fats, as mutton-suet, goose-grease, human-fat, and hog's-lard: when these have been treated with ether, for the purpose of obtaining stearin from them, the ethereal liquors, by spontaneous evaporation, deposit a portion of the solid matter which they contain, and this is to be collected on a linen cloth, strongly pressed, and then exposed for a long time to the heat of a salt-water bath. This substance is very soluble in cold ether, which distinguishes it from stearin. It consists of margaric acid united with glycerin.

MARGARON, a solid white fatty matter which crystallises in pearly scales, and is obtained by distilling margaric or stearic acid with excess of lime. It fuses at about 170° Fahr., is volatile, soluble in fifty times its weight of hot alcohol, and five times its weight of boiling ether. Exposed to the action of heat in close vessels it distils almost unchanged: it burns in the air with a brilliant flame. Nitric acid acts but slightly upon it; sulphuric acid chars it, and sulphurous acid is given out. The alkalies do not act upon margaron.

This substance is composed of—Hydrogen, 13.42; Carbon, 83.37; Oxygen, 3.21.

MARINE ACID. [CHLORINE; HYDROCHLORIC ACID.]

MARINE GLUE. [GELATINE.]

MARINE INSURANCE. [INSURANCE, MARINE.]

MARINER'S COMPASS. [COMPASS.]

MARINER'S CONTRACT. [SHIPS.]

MARINES, men embodied to serve as soldiers on board of ships of war in naval engagements; and on shore, in the event of a descent being made upon an enemy's coast. In the British service, they also assist occasionally in performing some of the operations connected with the working of the ship; they cannot however be sent aloft at the command of a naval officer.

Originally in this country, as well as in France, the national fleets were composed of merchants' ships, which were armed on occasion for war; and then there were no soldiers particularly destined for the naval service. The first troops of this kind in France were men skilled in the practice of the useful trades, who, when unemployed by the government, lived on shore on half-pay; receiving only the full pay when called upon to serve at sea. This regulation did not however long subsist; and, subsequently to the administration of Cardinal Richelieu, companies of marine soldiers have been constantly retained on full pay.

It is not precisely known at what period distinct corps were appointed in Britain to this branch of the public service. In 1684 mention is made of the duke of York's maritime regiment of foot; and in the reign of William III. several regiments were placed on the establishment of the navy, but these were subsequently disbanded. At that time the marine soldiers seem to have been retained as persons in training to become good seamen; and, in Burchet's 'Naval History,' quoted by Grose ('Mil. Antiq.,' vol. i.), it is said that they were discharged from the regiments and entered on the ship's books as foremast-men as soon as they became qualified to serve as such.

In the beginning of Queen Anne's reign (1702), six regiments of maritime soldiers were raised; and among the regulations concerning their service it is stated that they were to be quartered, when on shore, near the principal seaports. Whether at sea or on shore, they were to be paid at the same rate as the land forces, and the same deductions were to be made for clothing. At sea they were to be allowed pro-

visions equal in every respect to the shares of the seamen, without suffering any diminution of pay on that account.

In 1749, the then existing regiments of marine soldiers, ten in number, were disbanded; and six years afterwards, on the recommendation of Lord Anson, there were raised 130 companies, consisting in all of above 5000 men, who were put under the immediate command of the lords of the admiralty, and whose head-quarters were appointed to be at Plymouth, Portsmouth, and Chatham. The corps of marines, as it was then called, has subsequently been considerably increased; in 1759 it numbered 18,000 men; and during the war at the beginning of this century, its strength amounted to about 20,000 men. An additional division was, by an order of council in 1805, established at Woolwich; and there were two companies of marine artillery, whose head-quarters were at Portsmouth. At present there are four divisions of royal marine light infantry, and one division of royal marine artillery, the head-quarters of the latter being at Portsmouth. The total strength is 17,459 non-commissioned officers and privates, 435 commissioned officers, and 106 staff officers.

The marines are now clothed and armed in the same manner as the infantry of the line, and, like all the other royal regiments, their scarlet uniform has blue facings. The marine artillery are dressed in blue with white facings. In an engagement at sea, they annoy the enemy by a fire of musketry from the tops and deck; and they repel with the bayonet any attempt to board the ship. The gallant jollies, as the marines are familiarly called, have often distinguished themselves when acting on shore; and their meritorious services at the taking of Belle-isle (1761), in the battle of Bunker's Hill (1775), in the defence of Acre (1799), and under Lord John Hay, on the coast of Spain, have earned for them a lasting reputation.

The corps is commanded by a deputy adjutant-general, who is assisted by an assistant adjutant-general, and is under the admiralty. There are also five colonels-commandant of divisions, besides five colonels second commandants. No commissions in the corps are obtained by purchase; and the officers of marines rise in it by seniority, as high only however as the rank of colonels-commandant.

MARIOTTE, LAW OF, also known as Boyle's law, refers to the law of elasticity in gases, and may be thus expressed: "The volume of an æriform body is *inversely*, and its elasticity *directly*, as the pressure to which it is exposed." Hence, by doubling the pressure, we halve the volume; by trebling it, it becomes reduced to one-third; but by doubling the pressure we double the elasticity, by trebling the pressure we increase it three-fold, and so on. For those gases which have not been liquefied, or liquefied only under enormous pressures, the experimental results are nearly in strict accordance with the law, even under a pressure of several atmospheres. Such, however, is not the case for gases which readily liquefy. The nearer they approach the point of liquefaction the greater is the difference between the observed volume and the calculated result. The contraction is found to be more considerable than it should be if the law were strictly true. [AIR; ELASTICITY.]

MARITIME LAW. [ADMIRALTY COURTS; SHIPS.]

MARK, ST., THE GOSPEL OF. The genuineness and authenticity of this Gospel are attested by the unanimous voice of ecclesiastical writers. Michaelis has indeed objected to its canonical authority, in common with that of Luke, but on no good ground. According to Papias, Irenæus, and other early writers, Mark committed to writing the gospel which was preached by Peter; and Clement of Alexandria states that he did so at the request of Peter's hearers at Rome. Other early writers add that in this work Mark had the approbation and assistance of Peter; and many passages of the gospel have been thought to bear traces of being written under Peter's direction. From the tradition mentioned above, and from Latinisms and explanations of Jewish phrases and customs contained in Mark's gospel, it appears to have been written at Rome for the benefit of the Latin Christians.

The time when it was written is uncertain. Irenæus says that it was composed *μετὰ τὴν τούτων* (Peter and Paul) *ἐξόδον*; but whether he means *after the death* of Peter and Paul, or *after their departure* from Rome, is a question much disputed. Upon the whole, the most probable date appears to be about A.D. 64 or 66. There is little doubt that it was written after the Gospel of St. Matthew, and probably before the destruction of Jerusalem.

According to the unanimous testimony of the early ecclesiastical authors, the gospel of Mark was written in Greek. The Latin MS at Venice, said to be part of St. Mark's *autograph*, has long since been proved to be nothing of the kind.

The opinion that Mark's gospel is an abridgment of Matthew's has been satisfactorily refuted by Michaelis; for notwithstanding the coincidences between these two gospels, we find, on comparing them, that there are in Mark omissions of and discrepancies with what is contained in Matthew, which it is difficult to account for on the supposition that he wrote with the gospel of Matthew before him. The true mode of explaining these coincidences and discrepancies belongs to the more general question respecting the origin of the first three gospels. Those who believe that each evangelist composed his narrative from independent sources of information have no difficulty in proving Mark's qualifications for the task; for besides the assistance which he probably received from Peter, what we know of his life

proves that he must have had opportunities of constant intercourse with the apostles and first Christians.

(Lardner's *Credibility and Lives of the Apostles and Evangelists*; Cave's *Lives of the Apostles and Evangelists*; Kuinoel, *Comment. in Lib. Hist. N. T., Proleg. in Marc.*; Introduction to the Gospel according to St. Mark, in the *Pictorial Bible*, by Dr. Kitto, edit. 1849; and the *Introductions of Michaelis, De Wette, Hug, and Horne.*)

MARK. [MONEY.]

MARKET (*mercatum*), a public place and fixed time for the meeting of buyers and sellers. A legal market can exist only by virtue of a charter from the crown or by immemorial user, from which it will be presumed that a royal charter once existed, although it can be no longer produced. A market is usually granted to the owner of the soil in which it is appointed to be held, who, as such grantee, becomes the owner, or lord, of the market. In upland towns, that is, towns which, not being walled, had not attained the dignity of boroughs, markets were frequently granted to lords of manors; but in walled towns or boroughs, particularly in such as were incorporated, the ownership of the soil having usually, by grant from the crown, or other lords of whom the borough was originally holden, been vested in the incorporated burgesses, the course has commonly been to grant markets to the municipal body.

The prerogative of conferring a right to hold a market is however subject to this limitation, that the grant must not be prejudicial to others, more especially to the owners of existing markets. In order that the crown may not be surprised into the making of an improper grant, the first step is, to issue a writ *ad quod damnum*, under which the sheriff of the county is to summon a jury before him to inquire whether the proposed grant will be to the damage of the king or any of his subjects. This writ must be executed in a fair and open manner, and the sheriff is bound to receive evidence tendered against, as well as in favour of the grant. But as the writ does not purport to affect the interest of any person in particular, it is not necessary that notice should be given of the time or place at which it is meant to be executed. Notwithstanding a finding by the jury that the proposed market will not be injurious, any party who conceives that his interests are affected by the grant when made, whether he appeared upon the inquiry under the writ *ad quod damnum* or not, may traverse the finding, or sue out a writ of *scire facias*, which, after reciting the alleged injury, calls upon the grantee, in the name of the crown, to show cause why the grant should not be cancelled. If a new market be set up without any grant from the crown, the party is liable to be called upon by the crown to show by what warrant he exercises such a franchise [*LIBERTY; QUO WARRANTO*]; and he is also liable to an action on the case for damages, at the suit of any person to whose market, or to whose property, the market so set up by the defendant is a nuisance. A new market is presumed to be injurious to another held within the distance of twenty miles, even though it be on a different day, but this presumption may be rebutted.

Formerly markets were held chiefly on Sundays and holidays, for the convenience of dealers and customers, brought together for the purpose of hearing divine service. But in 1285, by 13 Edward I., c. 5, fairs and markets were forbidden to be held in churchyards; and in 1448, by 27 Henry VI., c. 5, all showing of goods and merchandise, except necessary victuals, in fairs and markets, was to cease on the great festivals of the church, and on all Sundays, except the four Sundays in harvest. The holding of fairs and markets for any purpose on any Sunday was prohibited in 1677, by 29 Charles II., c. 7.

The grantee of a market has a court of record called a court of pie-powder (*pieds pouldreux*, "dusty feet"), for the prompt decision of matters arising in the market. [*PIE-POWDER COURT.*] Such a court being considered necessary for the expedition of justice and for the support of the market, the power of holding it is incident to a grant of a market, even though the royal letters patent by which the grant is made be entirely silent on the subject.

Sales in markets may be of goods actually brought within the precincts of the market, or of goods not so brought. Goods not within the precincts of the market are sold sometimes by sample, sometimes without sample. Where goods are usually brought into the market for sale, it is incumbent on the lord of the market to take care that every thing be sold by correct and legal weights and measures.

For the security of dealings in markets, contracts were formerly required to be made in the presence of an officer appointed for that purpose by the lord of the market, for which service he received from the buyer a small remuneration called market-toll. [*TOLL.*]

It is a rule of the common law that every sale in market-overt (open market) transfers to the buyer a complete property in the thing sold; so that however defective the title of the vendor may be, yet that acquired by the vendee is perfect, even where the property belongs to a person who is under legal disability, as an infant, a married woman, an idiot, or a person in prison or beyond sea. In London every shop is market-overt for goods usually sold there.

This rule is subject to certain exceptions and restrictions. A sale in market-overt does not bind the rights of the crown; nor does it bind the rights of others, unless the sale be in an open place, as a shop, and not a warehouse or other private part of the house, so that those who go along cannot see what is doing, and not in a shop with the shop-door or windows shut, so that the goods cannot be seen. The articles

bought must be such as the party usually deals in. The sale must be without fraud on the part of the buyer, and without any knowledge on his part of any want of title in the vendor. If the seller acquire the goods again, the effect of the sale in barring the true owner is defeated. There may be a sale and contract; and therefore the property is not altered in market-overt in goods given, or in goods pawned, or in goods sold to the real owner. The sale must be between sunrise and sunset; and must be commenced and completed in the market.

By 21 Henry VIII. c. 2, "If any felon rob or take away money, goods, or chattels, and be indicted and found guilty, or otherwise attainted upon evidence given by the owner or party robbed, or by any other by their procurement, the owner or party robbed shall be restored to his money, goods, or chattels." Since this statute, stolen goods, specified in the indictment, have, upon the conviction of the offender, been restored to the prosecutor, notwithstanding any sale in market-overt.

As stolen horses can be easily conveyed to distant markets, the legislature has frequently interposed to protect the owner against the consequences of a sale in market-overt. Thus, by 31 Elizabeth, c. 12, "No person shall in any fair or market sell, give, exchange, or put away any horse, mare, &c., unless the toll-taker, book-keeper, bailiff, or other chief officer will take upon him perfect knowledge of the person that shall so sell, give, or exchange any horse, &c., and of his true name, surname, and dwelling-place, and shall enter the same in a book there kept for sale of horses; or else that he so selling or offering to sell, &c., any horse, &c., shall bring unto the toll-taker or other officer aforesaid of the same fair or market, one sufficient and credible person, that can testify before such toll-taker, &c., that he knows the party that so sells, &c., such horse, &c., and his true name, surname, mystery, and dwelling-place, and there enter in the book of the toll-taker or officer, as well the true name, surname, mystery, and place of dwelling of him that so sells, &c., such horse, &c., as of him that so shall testify his knowledge of the same person, and shall also enter the true price that he shall have for the same horse, &c." And by sect. 4, "If any horse, &c., be stolen, and afterwards sold in open fair or market, and the sale shall be used in all points and circumstances as aforesaid, yet the sale of any such horse, &c., within six months after the felony, shall not take away the property of the owner, so as claim be made within six months, before the mayor or other head officer of the town or parish, if the horse, &c., happen to be found in any town corporate or market-town, or else before any justice of peace of the county near to the place where such horse, &c., shall be found, if it be out of a town corporate or market-town, and so as proof be made within forty days, by two sufficient witnesses, before such head officer or justice, that the property of the horse, &c., so claimed, was in the party by whom such claim is made, and was stolen within six months next before such claim, but that the party from whom the horse, &c., was stolen may at all times after, notwithstanding any sale in fair or market, have property and power to take again the said horse, &c., upon payment or offer to pay the party that shall have the possession and interest of the same horse, &c., if he will accept it, so much money as the party shall depose and swear before such head officer or justice of peace, that he paid for the same *bonâ fide* without fraud or collusion." This statute extends to a horse taken by wrong, though it be not stolen.

A market is generally appointed to be held once, twice, or three times in a week, for the current supply of commodities, mostly of provisions. A large market held once or twice a-year is called a fair; and, according to Lord Coke, a large fair held once a-year is a mart.

Fairs have all the legal incidents of markets, and are subjected to further regulations by 2 Edw. III. c. 15, one of which requires, that at the opening of the fair, proclamation be made of the time it is to continue.

MARKETS, AGRICULTURAL. The more numerous markets are in any well cultivated country, provided they are at a sufficient distance not to interfere with each other, and on different days of the week, the greater saving there is of time and labour of conveyance. Good roads or navigable rivers are of great importance to a market-town; and if there are mills in the neighbourhood, where corn can be ground, they will increase the advantage to the farmer by causing a regular demand above what the immediate consumption of the place may require.

The vicinity of a good market where every kind of agricultural produce will always find purchasers at a fair price, greatly adds to the value of a farm, especially if good roads lead to it; and the advantage is the greater if it be a populous town, which not only consumes much produce, but from which various kinds of manure may be brought by the teams which have carried the produce to market.

It is perhaps for the general advantage that the farmers should bring their corn in regularly, without speculating on a rise or fall of prices. Nevertheless they may be safely left to follow the dictates of their own judgment, influenced as that is by the rise and fall of prices, which are the only indications we have of the demand requiring supply. The farmer is tempted to withhold his corn when the price is low, in order to have a greater profit when it rises; and, to a certain degree, he is justified in doing so: but if he speculates on his own corn, when he can obtain a fair price for it, he becomes a merchant, as much as if he purchased to sell at a profit. When there is a good market at hand,

the produce of the farm should be regularly sold, so as to give the farmer a constant supply of money for his operations, besides a portion set apart for the rent and other regular payments. In this way he will, at the end of the year, have had the average price, without risk and without speculation; and by a little caution he may obtain somewhat more than a mere average, provided he has always more money at hand than his immediate wants require, and is never forced to sell.

In order that the farmer may not be imposed upon, he must either make himself acquainted with the transactions in different neighbouring markets, or he must rely on the honesty and judgment of an agent, whose business it is to attend markets and buy and sell for others. These men are generally called salesmen or factors, and when their character for honesty is established, the small sum which is paid them on the sales will generally be found to be fully compensated by the advantage which their knowledge of the markets and of the quality of the articles gives them. This is particularly the case in the buying and selling of live-stock, which requires much more knowledge and experience than most other articles. The people whom the farmer has to deal with in fairs and markets have generally a thorough knowledge of the real value of the articles offered for sale, by constantly frequenting markets, and confining their attention to buying and selling only. The farmer is therefore seldom a match for the dealer, and will find it his interest to employ a person equally skilled in these matters. The farmer would lose too much valuable time, and be led to unnecessary expense, if he attempted to obtain the requisite knowledge by frequenting different and distant markets, as the dealers do.

Notwithstanding this, a certain knowledge of markets and prices is necessary to enable a farmer to detect imposition or ignorance in the person he employs, and the occasional attendance at fairs and markets is indispensable to obtain this knowledge.

When the whole bulk of the articles to be sold is brought into the market and exposed for sale, the market is called a *pitched* market; when only a small portion is brought, to show the quality of the whole, it is called a *sample* market. Each has its peculiar advantages and inconveniences. In a pitched market the buyer sees what he purchases, and can thoroughly examine it; he may therefore be induced to offer a more liberal price; but it often happens that he has to carry a load away by the same road by which it was brought; the sacks also have to be returned, which causes frequent mistakes and losses; and there is an evident waste of time and labour. When the article is sold by sample there is more reliance on the honesty of the seller, and the buyer naturally keeps on the safe side, by offering somewhat less, as a kind of insurance against slight deceptions. The buyer keeps half the sample and the seller the other, that they may be compared with the bulk in case of any dispute. The seller sends the article sold on a day agreed upon; and if it is corn, the sacks are brought back when the waggon or cart returns home. The price is usually paid on the next market-day. In very large dealings the selling by sample is generally adopted; small quantities are usually pitched.

Great inconvenience still arises from the various measures used in different markets; and dealers require tables to reduce them to one standard. The law which has established one uniform standard of weights and measures does not enforce its adoption, and a great variety of weights and measures still remains to perplex the dealer.

MARL, an earthy substance found at various depths under the soil, and extensively used for the improvement of land. It consists of calcareous and argillaceous earth, in various proportions, and as the former or the latter prevails, so it is beneficially employed on clays or sands. There are several distinct sorts of marl—clay marl, shell marl, slate marl, and stone marl. The clay marl has probably been formed by the slow deposition of clay suspended in water, and mixed with the particles of decomposed shells. When these shells have retained their form, or appear in fragments in the marl, it is called *shell marl*. A considerable compression and a complete decomposition of the shells form slate marl and stone marl. The effect of marl is the same as that of clay and chalk upon sandy soils; on heavy soils its effect is proportioned to the quantity of calcareous earth which it contains. The peculiar advantage of marl is its readily crumbling to powder by the effect of air and moisture. If it is too compact to dissolve under these influences, it can only be made useful by burning, and in this case it is only a substitute for lime, its value depending on the proportion of calcareous earth in the marl.

Marl is often found very near the surface, so as to mix with the soil in ploughing; but unless there be a sufficient depth of soil above, its presence does not indicate great fertility. It is generally best when found at a moderate depth, so as to be readily dug out and carted on the adjacent lands. In Norfolk, where a marl containing a large proportion of clay is found in many places under a light soil, it is frequently spread over the surface at the rate of two or three hundred cart-loads per acre. This dressing, joined to underdraining, makes a wonderful improvement on soils which before were scarcely worth cultivating, owing to their being loose and wet in winter. The clay marl makes them retain sufficient moisture, while the superfluous water is carried off by the drains.

Marl when put fresh upon the land requires some time in order to become effective. It should therefore be laid on the surface and spread before winter, leaving it there for a considerable time before it is ploughed in. It is most advantageous to put it on the land when it is

in grass, and to roll and harrow it repeatedly, in order to expose it to the effect of the air and rains. Alternate frosts and thaws greatly assist its pulverisation.

An excellent use of marl is in forming composts with dung and peat earth. It is laid in layers with the dung and peat, and if the heap is well soaked with urine or the washings of stable-yards, it will in a short time become a most valuable manure for all kinds of soils. Many peat bogs are formed on a marly bottom; where this is the case, and it can be drained, or the water got rid of in any way, the marl, when laid on the surface, consolidates the peat by its pressure, and soon makes it capable of producing good herbage by converting it into a rich vegetable mould.

The expense of marling land can only be calculated when the distance of the marl and the depth from which it is raised are known; when it lies in a stratum under the land, it is generally the cheapest plan to open a pit in each field; for the carriage of the marl is the chief expense. Within a distance of two hundred yards from the pit, it is found by experience that the cheapest way of putting it on the land is by means of men wheeling it in barrows with the help of planks, as is done in digging canals and other similar public works.

It is in the compound character of certain limes that the subject of marling becomes connected with that of liming. As extraneous matters increase in quantity, and the lime diminishes, the effect of the application of course depends less and less on those considerations which explain the effect of liming, and the influence of the application of marl depends more and more upon the clay or sand, or it may be other things in smaller quantity which are thus conveyed to the land.

In a great many, perhaps the majority of instances, marl owes its fertilising influences to the lime which it contains, and then its effects are precisely those which lime would produce—sweetening herbage, increasing the quantity and improving the quality of crops. This it cannot do so energetically as is done by caustic lime, what lime it contains being in a state of carbonate: its dilution however, by other earthy matters gives it almost as great facility of mixture with the soil as is possessed by caustic lime on its reduction to powder by slaking.

In so far, however, as marling acts by its calcareous ingredient, its use has been supplanted by that of burnt limestone; and the marl pits of the country in Devonshire, Worcestershire, Staffordshire, Cheshire, Surrey, Sussex, Kent, and other counties, now have, many of them, large trees growing in them, proving how long a time has elapsed since they were used. Accordingly, where the use of marls still prevails, and it certainly does prevail to a very large extent in some districts in England, their effect is chiefly due to the other ingredients which they contain. We will specify a number of instances in which the fertilising effects of this application have been apparent. Holkham Park, in Norfolk, was let in 1776, to Mr. Brett, at 3s. per acre, and on the expiry of his lease, it was offered to him at an advance of 2s.; he refused to take it, and Mr. Coke, the landlord, took it into his own hands. The surface soil of the whole district is very light sand, but nearly throughout it there is a stratum of rich marl, at various depths underneath. Pits accordingly were opened, and the marl dug out and laid upon the surface. This not only increased its fertility, but gave to the soil the solidity which is essential to the growth of wheat. Here then the effect was due, not merely, nor perhaps chiefly, to the lime which this marl contained, but to its clayey part, which corrected the excessive looseness of the top soil. Take another instance of the effect of clays upon light sandy soil. In some of the lighter districts of Lincolnshire, it has been long a common practice to apply the white clay on the chalky soils in its neighbourhood, and the blue marl which lies in their valleys to alter and improve the nature of their red sandy soil. The white buttery marl used in these localities gives both strength and solidity to the lighter soil on the green-sand formation, and in a particular instance in our knowledge a farmer having applied it only to two lands in one of his fields, found that the yield of corn from those lands was fully 2 or 3 sacks per acre greater than from the remainder of the field. The marl is also found to prevent the clubbing of turnips, or the disease called fingers and toes, to which that land was subject. The blue marl is beneficial, but in a less degree. It is common to put on 40 loads per acre, and one dressing of the white clay is found to be amply sufficient for a great many years, it being questionable whether a second application on the red land is calculated to be useful.

In Suffolk the marl, which is clay containing small particles of chalk, is generally applied to the light soils, where it improves the mechanical texture of the soil, stiffens the straw of wheat, prevents the finger and toe in turnips, and seems to add the food which clover requires.

Take now the instance of marl applied upon peaty soils throughout the fens of Cambridgeshire and Lincolnshire. The best method is to dig trenches in the soil some two feet wide at intervals of 20 to 30 feet, taking one or two feet of clay out of them and spreading it over the surface; 100 cubic yards may thus be spread for 30s. to 35s. per acre. The light fen soil will after this grow first-rate crops of wheat, flax, and even beans. And even where the same crops are retained in cultivation, their greater produce amply repays the cost of the operation putting that at 50s. per acre or 6d. per cubic yard of the clay applied.

In illustration of the quantity of clayey marl which is put upon light and fen land in some districts of the country, we may name the

case of Mr. Edward Witt, of Foreham, Suffolk, who has during six years applied on 183 acres of arable land nearly 52,000 loads, of 24 bushels each, at a cost of 463*l.* in manual labour; this is an average of 283 loads per acre of a cost of 50*s.* The West Suffolk Agricultural Society offers a prize of 4*l.* to the tenant who shall have carried and spread the greatest number of loads of clay during the previous twelve months, and a list for many years, given in the 8th vol. of the English Agricultural Society's Journal, shows the universality of the practice on light and fen land farm.

As a last illustration of the practice of marling we may refer to the use of chalk, which, though in some cases it must act chiefly by the lime which it contains, as when brought by railway out of Hampshire and applied at a cost of 4*s.* per ton, on the light lands of Surrey, is nevertheless used in large quantities where it can hardly be supposed that its usefulness depends upon its lime; as for instance on the chalk wolds of Lincolnshire, of Dorsetshire, and of Hampshire, where a dressing of 80 or of 100 cubic yards of chalk at a cost of less than 3*l.* per acre is spread upon the land: this with boning and feeding off with sheep being the means on which the farmer depends for fertility. The boning and sheep feeding are in constant operation; chalking is done at considerable intervals of time. One chalk is found to be much better than another for use in this way; differences which seem to indicate that their fertilising influence is not owing merely to their lime, but to some other ingredients—probably phosphate of lime, which is found in some chalk marls in considerable quantity. Thus, thanks to the researches of Messrs. Paine and Way into the chemical and agricultural character of the chalk formation, we have learned the existence of marl, containing very considerable proportions of phosphoric acid combined with lime, to which undoubtedly, and not to the carbonate of lime which it also contains, its fertilising influence is due. We may also mention as an illustration of the way in which the farmer may be misled by terms, that in this same district a bed of white earth is quarried and used upon the sandy lands of the locality with the best effect, which is called a marl, although hardly a trace of lime exists in it; the effect being no doubt due to the large proportion of the soluble silica which it is found to contain. It may be noticed that the shelly sand of the shore is largely used in Cornwall and on some parts of the Irish coast, and carried many miles inland, with the best effect on the fertility of the limeless soils to which it is applied.

MARMALADE, a sort of preserve, made with sugar and the Seville or bitter orange, a variety of the fruit of the *Citrus Bigaradia*. It is more wholesome when properly made—that is, when the rind is soft—than most other sweet preserves, as the bitter communicates tonic and stomachic properties to it.

The above is totally distinct from the material prepared from the *Ægle Marmelos*, a native fruit of India, which is there extensively used by the natives against diarrhoea and dysentery. It much resembles rhubarb in its properties, and, according to the dose, acts either as an astringent or mild laxative. It is now introduced into England, and used as a dietetic.

MARONITES, the name of a community of Christians belonging to the Western or Roman Church, and living on Mount Lebanon. They are neighbours of, and allied to, and in some places mixed with, the Druses, and, like them, independent in great measure of the Turkish power. The Maronites occupy the valleys and fastnesses of the principal ridge of Lebanon east of Beyroot and Tripoli, and they extend inland as far as the Bekaa, or plain between the Libanus and Anti-Libanus, where they are mixed with the Druses, though they do not intermarry with them. The tract of country in which the great bulk of the Maronites reside is called Kesrouan. It extends along the ridge of Libanus from the Nahr el Kelb, a stream which enters the sea 12 miles north of Beyroot, to the Nahr el Kebir, which enters the sea north of Tripoli, near the island of Ruad, the ancient Aradus, on which side the Maronites border on the Nosaïris, or Ansarieh, who extend to the northwards towards Latakiah, and the Ismaelians, who live farther inland near the banks of the Orontes. To the eastward the Maronites have for neighbours the Metualis, a tribe of independent Moslems, of the sect of Ali, who live under their own emir, and occupy the belad or district of Baalbek and part of the Anti-Libanus; and on the south they border on the territory of the Druses, with whom they form one political body. [DRUSES.] In their internal concerns the Maronites are governed by their own sheiks, of whom there is one in every village, from whose decision there is an appeal to the bishops, who have great authority, and in some cases to the emir of the Druses, and his divan, or council. The clergy are very numerous; the secular parish clergy are married, as in the Greek Church; but the regular clergy, who are said to amount to 20,000, and are distributed among about 200 convents, follow the rules of St. Anthony, and are bound by vows of chastity and obedience. The Maronite monks are not idle; they cultivate the land belonging to their convents, and live by its produce. Every convent is a farm. The convents are under the jurisdiction of bishops, of whom there is one in every large village. The bishops are under the obligation of celibacy. The bishops collectively elect the patriarch, who is confirmed by the pope, and who resides at the convent of Kanobin, in a valley of the Libanus, south-east of Tripoli, where there is a printing-press, which furnishes the elementary books for the use of the Maronite schools. Not far from Kanobin is the large village of Eden, ten miles above which, and high up the

Libanus, is the famed clump of old cedars, called the "cedars of Solomon," of large dimensions, but now reduced to seven in number (Lamartine, 'Voyage en Orient'; Richardson), not including the younger and smaller ones. Dr. Richardson measured the trunk of one of the old trees, and found it 32 feet in circumference. The whole clump of old and young trees may be walked round in about half an hour. Old cedars are not found in any other part of Libanus.

The Maronites derive their name from a monk of the name of Maro, who, in the 5th century collected a number of followers, and founded several convents in these mountains. When the Monothelite heresy prevailed in the East in the 7th century, and was favoured by the court of Constantinople, many Christians who did not embrace its tenets took refuge in the fastnesses of Libanus, around the convents, and thus the name of Maronites was assumed by the population of the mountains. This is the account of the Maronites themselves; others pretend that the Maronites were Monothelites, who took refuge in the Libanus after the Emperor Anastasius II. had condemned and proscribed their sect, in the beginning of the 8th century. [EUTYCHIANS.] Joseph Simonius Assemani, and his friend Ambarach, better known as Father Benedetti, have defended the Maronites from the charge of Monothelitism. Ambarach translated from the Arabic into Latin the work of Stephen, patriarch of Antioch, concerning the origin and the liturgy of the Maronites. In 1182 they were re-admitted to the communion of the Roman Church; and in 1736, at a great synod held at Marhanna, the Maronite Church formally acknowledged the canons of the council of Trent, but they retained the mass in the Syriac language and the marriage of priests. Before that time they received the sacrament under both forms, as in the Greek Church. At mass the priest turns towards the congregation and reads the gospel of the day in Arabic, which is the vulgar tongue.

The Maronite population is said to be above 200,000 individuals, and to contain between 30,000 and 40,000 men fit for military service. Every Maronite is armed, and they are all soldiers in case of need. Their language is Arabic, and by their appearance and habits they belong to the Arabian race. They are a fine-looking people, high-spirited, civil and hospitable, especially towards European travellers, and perfectly honest. Robbery and other acts of violence are hardly known among them. (Jowett, Light, Lamartine, and other travellers in Syria.) But Kinnear, who visited them in 1839, says, "happily for them, their religion exempts, or rather excludes, them from military service, and they escape the heaviest of all the evils under which their country has suffered—the conscription" ('Cairo, Petra, and Damascus, in 1839'), though he concurs in the favourable character given of the people. It would thus appear that a period of repose had relaxed their warlike qualities; and this is confirmed to some extent by the events of June, 1860. In that month, the Druses attacked the Maronites, who, though superior in number, made but a feeble resistance. Deis el Kama, their capital, was besieged, many villages destroyed and their inhabitants massacred, while the Turkish troops stood by and refused to interfere to repress the outrages.

There is at Rome, on the Quirinal Mount, a convent of Maronite monks, who perform the service of the mass in the Syriac language, according to the liturgy of their country. This church was founded by Pope Gregory XIII., and is dedicated to St. John. The monastery serves as a college for young Maronites who go to Rome to study and take orders, after which they return to their own country. It is one of those exotic colonies which give a peculiar interest to the city of Rome.

The ceremonies of these Maronites of Rome on great festivals, their chanting in Syriac, and their curious musical instruments, are described by the Abbé Richard, in his 'Voyage en Italie.'

MARQUE, LETTRES DE. [PRIVATEERING.]

MARQUESS, a title of honour used in England and on the Continent. Persons who have this title in England are the second in the five orders of English nobility. The dukes only are above them. In parliament all peers have the same privileges, by whatever title they are known. Marquesses in England have this privilege above earls, that their younger sons are addressed as "my lord," as Lord Clarence Paget, Lord Robert Cecil.

All titles of honour seem to have been originally the names of important offices, or to have denoted persons invested with a peculiar political character. Marquess is generally supposed, as we think justly, though other origins have been suggested, to have designated originally persons who had the care of the marches of a country. [MARCHES.] In Germany the corresponding term is *markgraf* (margrave), which seems to be "lord of the marches."

There were no English marquesses before the reign of Richard II. In the reign of Edward III. a foreign marquess, the Marquess of Juliers, was made an English peer with the title of Earl of Cambridge, and this circumstance probably suggested to King Richard the introduction of this new order of nobility. The person on whom it was conferred was his great favourite, Robert de Vere, Earl of Oxford, who was created Duke of Ireland and Marquess of Dublin in 1385. But the title had no long continuance in him, for three years after he was attainted and his honours forfeited.

In 1397 one of the illegitimate sons of John of Gaunt was created Marquess of Dorset; but he was soon deprived of the title, and his son had only the earldom of Somerset. The title of Marquess of Dorset

was however revived in the same family in 1443, when, also, William de la Pole was made Marquess of Suffolk.

In 1470, John Nevil, Earl of Northumberland, brother to Richard Nevil, Earl of Warwick, the king-maker, was made Marquess Montacute; but he was soon after slain at the battle of Barnet, and the title became lost.

In 1475, Thomas Grey, Earl of Huntingdon, son to the queen of King Edward IV. by her former husband, was made Marquess of Dorset; and in 1489, Maurice Berkeley, Earl of Nottingham, was made Marquess of Berkeley. Henry VIII. made Henry Courtenay, Earl of Devonshire, Marquess of Exeter; and he made Anne Boleyn, a little before his marriage with her, Marchioness of Pembroke. William Parr, Earl of Essex, brother of Queen Catherine Parr, was created Marquess of Northampton by King Edward VI.; and William Powlett, Earl of Wiltshire, Marquess of Winchester.

All these titles had become extinct in 1571, except that of Marquess of Winchester. This title still continues in the male representative of the original grantee, though for a century or more it was little heard of, being lost in the superior title of Duke of Bolton.

Queen Elizabeth made no new marquess, nor did King James I. till the fifteenth year of his reign, when his great favourite George Villiers was created Marquess of Buckingham. Charles I. advanced the Earls of Hertford, Worcester, and Newcastle to be Marquesses of those places; and Henry Pierrepont, Earl of Kingston, was made Marquess of Dorchester.

Charles II. advanced the Earl of Halifax to be Marquess of Halifax in 1682; and James II. made the Earl of Powis Marquess of Powis in 1687.

A new practice in relation to this title was introduced at the Revolution. This was the granting of the title of marquess as a second title when a dukedom was conferred. Thus, when Schomberg was made Duke of Schomberg he was made also Marquess of Harwich; when the Earl of Shrewsbury was made Duke of Shrewsbury he was also made Marquess of Alton; and when the Earl of Bedford was made Duke of Bedford he was also made Marquess of Tavistock. There were many other creations of this kind in the reign of William III., and several of marquesses only. It is not intended to name all the instances, either in this or the subsequent reigns. Of the existing dukes, eleven have marquessates in the second title, which is borne by the eldest son during the life of the father.

The only marquess who sits in the House of Peers as a marquess, and whose title dates before the reign of George III., is the Marquess of Winchester. The other marquesses, twenty-one in number, are all of recent creation, only seven dating from the last century, one of whom, Tweeddale, sits as a Scotch representative only, though most of them are old peers under inferior titles.

The title seems not to have been known in Scotland till 1599, when Marquesses of Huntley and Hamilton were created.

MARQUETRY and PARQUETRY, are two names for modes of grouping small pieces of wood into ornamental devices; the one for producing pictures and small decorative works, and the other for floors. During the middle ages, the specimens produced were generally alternations of black and white; but in the 15th century the Italians began to stain the pieces of wood in various colours, so as to afford facilities for much diversity of pattern. Afterwards, many of the beautiful woods of America were brought into use; and a method of representing shadows was devised, by scorching or singeing portions of the surface. In some examples the pieces of wood employed were so small, and the colours so selected, as to admit of the representation of landscapes and other pictorial subjects, in a certain rude way. Most marquetry work is a delicate kind of veneering. The ground-work is of well-dried oak or fir, secured from warping. The coloured woods are sawn into very thin plates and dyed or otherwise prepared. Supposing a flower in white wood on a black ground is to be produced by marquetry, there are three different modes adopted for cutting out the veneers to the proper shape. In the first method, a drawing or engraving of the device is cut into pieces; the pieces are pasted in proper position on two slabs of black and white veneer; and a very delicate saw, worked by a treadle, cuts the wood into the requisite shapes. In the second method the whole design is pasted on the black veneer; the leaves are cut out separately in white veneer, each white piece is pasted to the proper part of the paper, the black veneer is then cut through by a saw following the contour of the white pieces, the wood is separated from the paper, and lastly the white pieces are let into the holes cut in the black. In the third method a sheet of paper is pasted on the black veneer, upon this is placed a sheet of blackened or carbonised paper, and upon this again another sheet of white paper; the pieces of white veneer, properly cut, being pasted in proper position on the uppermost sheet of paper, a smart pressure or rolling will transfer a blackened device to the lowest sheet of paper sufficient to guide the sawing of the black veneer. The production of many-coloured marquetry will easily be understood from this description of the modes of cutting the veneers to produce black and white specimens. When the Italian and French marquetrymen produce pictures instead of mere geometrical or fancy patterns, the work is frequently called *tarsia-work*. Numerous kinds of wood are employed, and much staining and scorching are resorted to. Holly is a favourite wood, because it is nearly white, and receives staining or dyeing very readily. M. Cr  mer, a French marque-

trier, has in recent years produced many beautiful specimens, made of bits of veneer which had previously been dyed by Boucherie's process—that of causing the living tree to absorb saline and colour-producing solutions. At the Great Exhibition of 1851, many remarkable specimens of marquetry were shown—such as M. Bisso's table from Genoa, with a zodiac device on the top; M. Claudio's table from Nice, with four celebrated battles depicted in marquetry; an octagonal library table, made of 14,000 pieces of wood; and, most curious of all, the Spanish table made by M. Perez, of Barcelona, which was said to comprise no less than 3,000,000 minute pieces of wood.

Parquetry or *Parquetage* is a plainer kind of marquetry, little varied by colours, and applied as a flooring. The simpler varieties are said to have had their origin in a desire to avoid the warping of long narrow boards, by employing boards only three or four feet long by as many inches in width, and arranging them in various patterns. It rarely happens that there are more than two colours employed. Many old baronial halls exhibit flooring in which a smooth plain ground is adopted to show off a differently coloured wood cut into geometrical devices. Wood of one kind and colour is capable of yielding delicate patterns, something like that of a damask table-cloth, by placing the grain of the wood in different directions in different pieces. At Windsor Castle, the Royal Exchange, and other places, parquetry floors have been laid down in recent years. In some kinds the thin layers or veneers are fitted in stout oak frames formed into compartments comprising squares, diamonds, polygons, or any other desired shape; the oak frames are rather more than an inch in thickness, and the thick veneer is from a quarter to three-eighths of an inch thick. In other kinds no thin veneers are employed; the wood itself, not being costly, is used in pieces thick enough to be put together in a more expeditious and less costly way. There is a 'patent solid parquetry' now made in London for the flooring of mansions and public buildings, saleable at 1s. per square foot, for an inch in thickness.

The points of difference between small piece-meal productions in wood, metal, glass, enamel, and marble, will be understood by comparing the present article with INLAYING and MOSAIC.

MARQUOI'S RULERS. Among the methods which have been devised for facilitating the operation of drawing parallel lines, those which consist in making one ruler slide along the edge of another are in almost every case the most expeditious and accurate.

A triangular ruler, having two of its edges at right angles to one another, being made so to slide with one of its edges perpendicular to the length of a common rectangular ruler, constitutes, apparently, one of the first contrivances of this nature. It is said to have been originally employed in Germany, whence its use extended to other parts of Europe. A triangular ruler of the form just mentioned is called by the French artists an *  querre*.

The most approved construction and application of a triangular ruler are due to an artist named Marquoi, who resided in London, and by his name only the instrument is now known. Where many lines are to be drawn parallel and perpendicular to one another, as in making plans or elevations of buildings, or the horizontal projections of the ramparts of fortresses, such an instrument is particularly useful. The right-angled triangle, as well as the rectangular rulers which accompany it, is made of box-wood, ivory, or some metal; and on the surfaces of the latter rulers are certain scales with graduations in equal parts.

MARRIAGE is a contract by which a man and a woman enter into a mutual engagement, in the form prescribed by the laws of the country in which they reside, to live together as husband and wife during the remainder of their lives.

Marriage is treated as a civil contract even by those Christians who regard it as a sacrament, and as typical of the union between Christ and the church. The religious character of the transaction does not attach until there has been a complete civil contract, binding according to the laws of the country in which the marriage is contracted. The authority of the sovereign power in regulating and prohibiting marriages is therefore not affected by the super-induced religious character.

Among Protestants marriage has ceased to be regarded as a sacrament, yet in most Protestant countries the entrance into the marriage state has continued to be accompanied with religious observances. These are not however essential to the constitution of a valid marriage, any further than the sovereign power may have chosen to annex them to, and incorporate them with, the civil contract.

After the establishment of Christianity, in order to avoid the scandal of persons living together who were not known to be married, and also to secure and perpetuate the evidence of marriage, where really contracted, it became usual to make the marriage promise in the presence of the assembled people, and to obtain at the same time the blessing of the priest upon their union, except when one of the parties had been married before, in which case no nuptial benediction was anciently pronounced, the benediction once received by one party being considered sufficient to hallow the union as to both, unless by the distinction it was intended to intimate that second marriages, though tolerated, were not sanctioned by the church. So late however as the 12th century, in a decretal epistle of Alexander III. to the bishop of Norwich, the pope says, "We understand from your letter that a man and woman mutually accepted one another without the presence of any priest, and

without the observance of those solemnities which the Anglican church is wont to observe, and that before consummation of this marriage he had contracted marriage with another woman, and consummated that marriage. We think right to answer, that if the man and the first woman accepted one another *de presenti*, saying one to another, 'I accept thee as mine, and I accept thee as mine,' although the wonted solemnities were not observed, and although the first marriage was not consummated, yet the woman ought to be restored to her husband; since after such consent he neither should nor could marry another."

Private marriages, designated *clandestine* marriages by the clergy, continued to be valid till the Council of Trent, which, after anathematizing those who should say that private marriages theretofore contracted by the sole consent of the parties were void, decreed, contrary to the opinion of 56 prelates, that thenceforward all marriages not contracted in the presence of a priest and two or three witnesses should be void. This decree, being considered as a usurpation upon the rights of the sovereign power, which alone can prescribe whether any and what formalities shall be required to be added to the consent of the parties in order to constitute a valid marriage, has never been received in France and some other Roman Catholic countries.

A marriage was clandestine if contracted otherwise than in public, that is, in *facie ecclesie*; and it was called an *irregular* marriage if it was clandestine, or if, though not clandestine, it was contracted without the benediction of a priest in the form prescribed by the rubric, the intervention of a priest having latterly been required in all cases, even though one of the parties were a widower or a widow. Clandestinity and irregularity subjected the parties to ecclesiastical censures, but did not affect the validity of the marriage.

The decrees of the Council of Trent had no force in England. A marriage by mere consent of parties, until the passing of the Marriage Act in 1753, constituted a binding engagement; though if application were made to the ecclesiastical courts for letters of administration, &c., under a title derived through such irregular marriage, those courts sometimes showed their resentment of the irregularity by refusing their assistance, more especially where the non-compliance with the usual formalities could be traced to disaffection to the Established Church. What the formalities required by the Church before the Marriage Acts were, it is now immaterial to consider. Such of them as are not incorporated into any of the Marriage Acts, are now of no force for any purpose.

To constitute a valid marriage, as well before as since the Marriage Acts, it is necessary, 1st, that there should be two persons capable of standing in the relation of husband and wife to each other; 2ndly, that they should be willing to stand in that relation; and 3rdly, that they should have contracted with one another to stand in that relation.

1. The capacity of standing in the relation of husband and wife implies that at the time of the contract there should be no natural or legal disability. Total and permanent disability on either side to consummate marriage will render the contract void. Temporary disability from disease does not affect the validity of a marriage. Temporary disability from defect of age does not invalidate the marriage, but it leaves the party or parties at liberty to avoid or to confirm such premature union on attaining the age of consent, which for males is 14, and for females 12. Before the abolition of feudal tenures, when the lords were entitled to sell the marriages of their male and female wards, infantine marriages were very common, fathers being anxious to prevent wives and husbands from being forced upon their children after their death, and lords being eager, either to secure the prize for their own family, or to realise the profit resulting from a sale. A person who is already married is under a legal disability to contract a second marriage whilst the first wife or husband is alive; and although there may have been the strongest grounds for believing that the first wife or husband was dead, the children of the second marriage would not in England derive any benefit from the absence of moral guilt in their parents, though in France and some other countries the issue of marriages so contracted, *bonâ fide*, are treated with greater indulgence.

Near consanguinity or relationship in blood is a legal impediment to marriage. The degree of nearness which shall disable parties from uniting in marriage varies in different countries, and has varied at different periods in our own.

This impediment is founded not only upon the moral but upon the physical constitution of man. The purity of domestic intercourse, the sanctity of affection with which the family circle is now united, would be at an end if matrimonial connections could be formed among its members; and even with the present restrictions intermarriages in families are frequently productive of the most injurious consequences in respect of mental and bodily health.

Affinity or relationship by marriage is an impediment arising out of moral considerations alone. The extent to which this impediment has been carried has also varied.

The impediment to marriage arising out of consanguinity applies in the same degree to illegitimate as to legitimate relations, and the impediment resulting from affinity is created by illicit connection as well as by marriage. The Council of Trent restricted the impediment of affinity arising out of illicit connection to the second degree.

2. Each party must have the will to contract marriage with the other. An idiot therefore, who cannot understand the nature of the

conjugal relation, is incapable of contracting marriage. So is a lunatic, except during a lucid interval. But however absurd it may appear, children are presumed to have sufficient intelligence to understand the nature of the marriage engagement at seven; and though the contract is not absolutely binding upon them until they reach the age of consent, still the marriage of a child above the age of seven would prevent its forming a second marriage until the age of consent, as until that age it cannot dissent from the first marriage.

3. There must be an actual contract of marriage. This, at common law, might be by words of present contract, which would, without more, constitute a perfect marriage,—or by words of future contract, followed by cohabitation.

The unlimited freedom of marriage was first broken in upon in England by the Marriage Act of 1753 (26 Geo. II., c. 33), the principal provisions of which form the basis of the law as it now stands. Many of these provisions are taken from the canon law, an observance of which was, before this statute, necessary to constitute a *regular* marriage, though a marriage contracted without them was *valid*.

The restrictions upon the common-law freedom of marriage are now embodied in two statutes.

The 4 Geo. IV., c. 76, contains the following provisions: Banns of matrimony are to be published in the church, or a public chapel in which banns are allowed to be published, of the parish or chapelry wherein each of the parties dwells, immediately after the second lesson of morning service, or of evening service if there be no morning service, upon three Sundays preceding the solemnisation (s. 2). Notice of the names of the parties, their place of abode, and the time during which they have dwelt there, is to be delivered to the minister seven days before the first publication (s. 7). Banns are to be republished on three Sundays, if marriage do not take place within three months after publication completed (s. 9). No licence of marriage (that is, dispensation from the obligation to publish banns) is to be granted to solemnise marriage in any church or chapel not belonging to the parish or chapelry within which the usual place of abode of one of the parties has been for fifteen days immediately before the granting of the licence (s. 10). Extra-parochial places are to be taken to belong to the parish or chapelry next adjoining (s. 12). Upon obtaining a licence, one of the parties must swear that he or she believes that there is no impediment of kindred or alliance (consanguinity or affinity), or of any other lawful cause, nor any suit commenced in any ecclesiastical court, to hinder the marriage, and that one of the parties has, for fifteen days immediately preceding, had his or her usual place of abode within the parish or chapelry; and where either of the parties, not being a widower or widow, is under the age of twenty-one, that the consent of the person or persons whose consent is required by that act has been obtained, or that there is no person having authority to give such consent (s. 14). The father, if living, of any party under twenty-one, not being a widower or widow, or, if the father be dead, the guardian or guardians of the person of such party, or one of them, and in case there be no guardian, then the mother of such party if unmarried, and if there be no mother unmarried, then the guardian or one of the guardians of the person appointed by the Court of Chancery, has authority to give consent to the marriage of such party; and such consent is required, unless there be no person authorised to give it (s. 16). In case of the father, guardian, or mother being *non compos mentis*, or beyond sea, or unreasonably or from undue motives refusing or withholding consent, any person desirous of marrying may petition the lord-chancellor, master of the rolls, or vice-chancellor; and in case the marriage proposed shall, on examination, appear to be proper, the lord-chancellor, &c., may judicially declare the same to be so; and such declaration shall be equivalent to consent of the father, &c. (s. 17). If a marriage be not had within three months after licence, marriage cannot be solemnised without a new licence or banns (s. 19). The archbishop of Canterbury is authorised to grant special licences to marry at any convenient time or place (s. 20). If any persons, knowingly and wilfully, intermarry in any other place than a church or such public chapel, unless by special licence, or, knowingly and wilfully, intermarry without the publication of banns and licence, or, knowingly and wilfully, consent to the solemnisation of such marriage by a person not being in holy orders, the marriage is null and void (s. 22). (It has been held, that in order to invalidate a marriage under this section, both parties must know the irregularity of the proceeding.) When a marriage is solemnised between parties, both or one of them being under age, by false oath or fraud, the marriage is valid, but the guilty party is to forfeit all property accruing from the marriage (s. 23). After the solemnisation of any marriage by banns or licence, no proof can be required of actual dwelling or usual place of abode, nor can any evidence be received to prove the contrary (s. 26). Marriages are to be solemnised in the presence of two witnesses besides the minister, and registered.

The principal provisions of 6 & 7 Will. IV., c. 85, which was passed chiefly in ease of those who scrupled at joining in the services of the Established Church, are these:—Marriages may be solemnised on production of the registrar's certificate, under the provisions of that Act, in like manner as after publication of banns (s. 1). In every case of marriage intended to be solemnised according to the rites of the Church of England, unless by licence or special licence, or after publication of banns, and in every case of marriage intended to be solemnised

according to the usages of the Quakers or Jews, or according to any form authorised by that Act, one of the parties is to give notice according to the form set out in the Act, to the superintendent registrar of the district or each of the districts within which the parties have dwelt for seven days then next preceding, stating the name and surname, and the profession or condition, and the dwelling-place of each, and the time (not less than seven days) during which each has dwelt therein, and the church or building in which the marriage is to be solemnised (s. 4).

After the expiration of seven days, if the marriage is to be solemnised by licence (that is, from the surrogate, or officer of the ecclesiastical court), or of twenty-one days, if without licence, the superintendent registrar, upon request, is to issue a certificate, provided no lawful impediment be shown, stating the particulars set forth in the notice, the day on which it was entered, that the full period of seven days or of twenty-one days has elapsed since the entry of such notice, and that the issue of such certificate has not been forbidden by any authorised person (s. 7). (This provision does not apply to marriages by licence celebrated according to the rites of the Church of England.) The like consent is required to a marriage solemnised by licence, as would have been required to marriages by licence before the passing of the Act (that is, by 4 Geo. IV., c. 76, ss. 16 & 17); and every person whose consent to a marriage by licence is required by law is authorised to forbid the issue of the superintendent registrar's certificate (s. 10). Every superintendent registrar may grant licences for marriage in any building registered within any district under his superintendence, or in his office (s. 11). Before any licence for marriage can be granted by a superintendent registrar, one of the parties must appear personally before him, and must, in case the notice of the intended marriage has not been given to the same superintendent registrar, deliver to him the certificate of the superintendent registrar or registrars to whom such notice has been given; and such parties must make oath, affirmation, or declaration, that he or she believes that there is not any impediment of kindred or alliance, or other lawful hindrance, to the marriage, and that one of the parties has for fifteen days immediately before the day of the grant of the licence (or rather the day of the making of the oath, &c.), had his or her usual place of abode within the district in which such marriage is to be solemnised; and where either party, not being a widower or widow, is under twenty-one, that the consent of the person or persons whose consent to such marriage is required by law has been obtained thereto, or that there is no person having authority to give such consent (s. 12). No marriage after notice, unless by virtue of a licence by the superintendent registrar, is to be solemnised or registered until after the expiration of twenty-one days after entry of notice, and no marriage is to be solemnised by the licence of any superintendent registrar, or registered, until after the expiration of seven days after the day of the entry of notice (s. 14). Whenever a marriage is not had within three calendar months after notice entered by the superintendent registrar, the notice and certificate, and any licence granted thereupon, and all other proceedings, become utterly void; and no person can proceed to solemnise the marriage, nor can any registrar register the same, until new notice, entry, and certificate (s. 15). The certificate of the superintendent (or superintendents) is to be delivered to the officiating minister, if the marriage is to be solemnised according to the rites of the Church of England; and such certificate or licence is to be delivered to the registering officer of Quakers for the place where the marriage is solemnized, if the same shall be solemnized according to their usages; or to the officer of a synagogue by whom the marriage is registered, if to be solemnised according to the usages of persons professing the Jewish religion; and in all other cases it is to be delivered to the registrar present at the marriage (s. 16).

Any proprietor, or trustee, of a separate building, certified, according to law, as a place of religious worship, may apply to the superintendent registrar, in order that such building may be registered for solemnising marriages therein; and in such cases he is to deliver to the superintendent registrar a certificate signed in duplicate by twenty householders, that such building has been used by them during one year as their usual place of public religious worship, and that they are desirous that the place shall be registered; each of which certificates is to be countersigned by the proprietor or trustee by whom the same is to be delivered, and the superintendent registrar is to send both certificates to the registrar-general, who is to register such building accordingly, and indorse on both certificates the date of the registry, and to keep one certificate with the other records of the general register office, and to return the other certificate to the superintendent registrar, who is to keep the same with the other records of his office; and the superintendent registrar is to enter the date of the registry of such building, and is to give a certificate of such registry under his hand, on parchment or vellum, to the proprietor or trustee by whom the certificates are countersigned, and is to give public notice of the registry thereof, by advertisement in some newspaper circulating within the county and in the 'London Gazette' (s. 18).

After the expiration of the twenty-one days, or of seven days, if the marriage is by licence (that is, from the surrogate), it may be solemnised in the registered building stated in the notice, between and by the parties described in the notice and certificate according to such form and ceremony as they may see fit to adopt, every such marriage to be solemnised with open doors between eight and twelve in the fore-

noon, in the presence of some registrar of the district in which the building is situate, and of two witnesses.

In some part of the ceremony, and in the presence of a registrar and witnesses, each of the parties is to declare—

'I do solemnly declare, that I know not of any lawful impediment why I, A. B., may not be joined in matrimony to C. D.'

And each of the parties is to say to the other—

'I call upon these persons here present, to witness that I, A. B., do take thee, C. D., to be my lawful wedded wife (or husband).'

Provided also, that there be no lawful impediment to the marriage of such parties (s. 20). Persons who object to marry in any such registered building may, after due notice and certificate issued, contract and solemnise marriage at the office of the superintendent registrar, and in his presence and in that of some registrar of the district, and of two witnesses, with open doors, and between the hours aforesaid, making the declaration and using the form of words as above (s. 21). After any marriage solemnised, it is not necessary, in support of such marriage, to give proof of the actual dwelling of either of the parties previous to the marriage within the district for the time required by the act, or of the consent of any person whose consent is required; nor is evidence admissible to prove the contrary in any suit touching the validity of such marriage (s. 25). The registrar before whom any marriage is solemnised according to the provisions of this act may ask of the parties to be married the several particulars required to be registered touching such marriage (s. 36). Every person knowingly and wilfully making any false declaration, or signing any false notice or certificate required by this Act, for the purpose of procuring any marriage, and every person forbidding the issue of any superintendent registrar's certificate by falsely representing himself or herself to be a person whose consent to such marriage is required by law, knowing such representation to be false, is to suffer the penalties of perjury (s. 38). If any person knowingly and wilfully intermarry under the provisions of this Act,—in any place other than the church, chapel, registered building, or office, or place specified in the notice and certificate,—or without due notice to the superintendent registrar,—or without certificate of notice duly issued,—or without licence, in case a licence is necessary,—or in the absence of a registrar, where the presence of a registrar or superintendent registrar is necessary, the marriage of such persons, except in certain excepted cases, is null and void (s. 42); as under 4 Geo. IV., c. 76, s. 22, a marriage would not be void unless both parties knowingly and wilfully concurred in marrying contrary to the provisions of the 42nd section. If any valid marriage be had under the provisions of this Act by means of any wilfully false notice, certificate, or declaration made by either party to such marriage, as to any matters to which a notice, certificate, or declaration is required, the attorney-general or solicitor-general may sue for a forfeiture of all estate and interest in any property accruing to the offending party by such marriage (s. 43). Consent to marriage may be withdrawn upon good reason; but it would rather appear that this cannot be done merely because the parent or guardian has changed his mind. The question of consent is not however of such vital importance as under the first Marriage Act (26 Geo. II., c. 33, s. 11), which made marriages without consent of parents, &c., absolutely void. Under 4 Geo. IV., c. 76, s. 23, and 6 & 7 Wm. IV., c. 85, s. 43, a false statement as to consent subjects the fraudulent party to the penalties of perjury, and to a forfeiture of all estate and interest in any properties accruing by the marriage, but leaves the marriage itself in full force.

The stat. 7 & 8 Vict., c. 86, provides for the licensing of district churches and chapels for the celebration of marriage. The stat. 19 & 20 Vict., c. 119, enables parties who have entered into the contract of marriage merely before the superintendent registrar to have the ceremonies of their church or persuasion added at any time afterwards. ('Black. Comm.' Mr. Kerr's ed., vol. 1, p. 464.)

These statutes do not extend to marriages contracted out of England, or to marriages of the royal family, which are regulated by a particular statute, 12 George III., c. 11.

Before 1835, marriages within the prohibited degrees of consanguinity and affinity were valid until annulled by a declaratory sentence of the ecclesiastical court, after which they became void ab initio, and the issue of such marriages were, by such sentence, rendered illegitimate; and the law is still so with respect to personal incapacity existing at the time of the contract. But as the ecclesiastical court could, professedly, only proceed *pro salute animæ*, and its authority to annul an incestuous marriage was founded upon the duty of putting a stop to the incestuous intercourse, the power of annulling the marriage ceased upon the death of either of the parties. The validity of such marriage, and the legitimacy of the issue, depended therefore upon the contingency of a suit being instituted and a sentence pronounced, during the joint lives of the husband and wife. But now, by 5 & 6 Will. IV., c. 54, all marriages thereafter celebrated between persons within the prohibited degrees of consanguinity or affinity are absolutely void to all intents and purposes. And, even at common law, a marriage contracted while there is a former wife or husband alive is ipso facto void, without any declaratory sentence.

Generally speaking, a marriage, valid according to the law of the country in which it was contracted, is valid in every other country.

This rule is however subject to some exceptions, as where marriages, contracted according to the law of the country (*lex loci*), are considered, in the courts in which their validity happens to be contested as contracted in violation of some principle of natural religion or morality, or as where, in Persia or Turkey, a man marries a second wife in the lifetime of the first.

A constitution of the emperor Constantine, restored in 476 by the emperor Zeno (*Cod.*, lib. 5, tit. 27, l. 5), enabled the husband of a concubina who had children by her, without having had any child *ex justis nuptiis*, to raise the concubina to the dignity of *justa uxor*, and to confer on those children the privilege of children born *ex justis nuptiis*, though actually born *ex concubinato*. This was carried still further when marriage was invested with a religious character. Its efficacy as a sacrament was regarded as so powerful, as to have a retrospective operation upon children born at the time when there was no semblance or intention of marriage of any kind, provided that at the time of the birth there existed no impediment to the marriage of the parents. Alexander III., who filled the papal chair from 1159 to 1181, pronounces that "Tanta est vis matrimonii, ut qui antea sunt geniti, post contractum matrimonium, legitimi habeantur." *Extravag.*, cap. 6, "Qui filii sunt legit." (Pothier, *Traité du Contrat de Mariage*.) This modification of the law of legitimacy, though frequently recommended by the clergy, was never adopted in England by the laity. It is however the law of Scotland as well as of France, and of most other Roman Catholic countries.

MARRIAGE, ROMAN. The right conception of the Roman institution of marriage and of its legal consequences is essential to enable us to approximate to a proper understanding of the old Roman polity.

Children were in the power of their father [*EMANCIPATIO*] only when they were the offspring of a legal marriage (*justæ nuptiæ*, or *justum matrimonium*). The cases of legitimation and adoption need not be considered here. To constitute such a legal marriage there must be between the parties *connubium*, the nature of which condition is best explained by an example:—Between a Roman citizen and the daughter of a Roman citizen there was *connubium*, and as a consequence the children of such marriage were Roman citizens, and in the power of their father. Between a Roman citizen and a female slave (*ancilla*) there was no *connubium*, and consequently the children which sprung from such a union were not Roman citizens. Whenever there was no *connubium*, the children followed the condition of the mother: when there was *connubium*, they followed the condition of the father. Various degrees of consanguinity, as the relation of parent and child, prevented *connubium* between parties in such a relation. After the Emperor Claudius had married Agrippina, his brother's daughter, such relationship was no longer an impediment to a legal marriage; but the license was carried no further than was warranted by the decree of the senate, and the marriage of an uncle with his sister's daughter remained, as before, an illegal union. (Tacit., *Annal.* xii. 7; Gaius, i. s. 62.) Further, to constitute a legal marriage, the two parties must be of sufficient bodily maturity; both parties also must consent, if they are capable of giving a legal consent (*sui juris*); or if not, their parents must consent.

The ceremonial parts of the marriage were of three kinds, by any one of which the wife was said to come into the hand of the husband (in *manum*), and to occupy the legal relation of a daughter. A woman who lived for one year with a man without interruption, became his wife by virtue of this cohabitation (*usus*). As in the case of all moveables, by the laws of the Twelve Tables, one year's enjoyment of a thing transferred the ownership of it, so by one year's uninterrupted cohabitation the husband acquired that interest in the wife which was the result of complete marriage. The Twelve Tables provided that if the wife wished to avoid the legal effect of this cohabitation, it was only necessary to absent herself from her husband for three nights during the year, which would be a sufficient legal interruption to the *usus*. In the time of Gaius, this part of the old law had been partly abolished by enactments, and had partly fallen into disuse.

The *Confarreatio*, so called from the use of a loaf of bread on the occasion, appears to have been of the nature of a religious ceremony, and it existed in the time of Gaius. It appears that certain offices, such as that of *Flamen Dialis*, could be held only by those who were born of parents who had been married by the ceremony of *Confarreatio*. (Gaius, i. 112; Tacit., *Ann.* iv., 16.)

The *Coemptio* was, in form, a sale (*mancipatio*) before five witnesses. [*MANCIPIMUM*.] The *Coemptio* might be made either between a woman and her intended husband, in which case she became, in contemplation of law, his daughter, or between a woman and a stranger (*fiduciæ causa*), which was a necessary legal process in case a woman wished to change one guardian for another, or to acquire the privilege of making a will. For until the *senatus consultum* passed in the time of Hadrian no woman could make a testamentary disposition (with the exception of certain privileged persons), unless she had contracted the *Coemptio*, that is, had been sold, and then resold and manumitted. The *Coemptio*, being effected by *mancipatio*, worked a legal change of status (*Dig.* 4. 5. 1), or *diminutio capitis*; and it was the least of the three kinds of *diminutio capitis*, or that by which a person underwent no change in

his civil capacity, except the being transferred into another family. (Paulus, *Dig.* 4. 5. 11.) This explanation will render intelligible the passage of Cicero on the testamentary power of women (*Topic.* 4), taken in connection with Gaius (i. § 115, &c.). The essays of Hoffmann and Savigny, in the *Zeitschrift für Geschichtliche Rechtswissenschaft*, vol. iii., p. 309, &c., may also be read with advantage.

A gift from husband to wife, or from wife to husband, was void (with some few exceptions). The transaction was the same as if nothing had been done. The *Donatio mortis causâ*, or *divortii causâ*, in contemplation of death, or in consideration of divorce, was a valid gift.

There could be no *dos* (marriage portion), unless there was *justum matrimonium*. The term *dos* comprehended both what the wife brought to the husband on her own account, and what was given or contracted to be given by any other person, in consideration and for the purposes of the marriage. (*Dig.* 23. 3. 76.) When the *dos* came from the wife's father, it was called *profecticia*, but when from any other person, *adventicia*. It was a general rule that the *dos adventicia* remained with the husband, unless there was some agreement to the contrary, in which case it was called *dos recepticia*. What came into the husband's possession, not as *dos*, was included in the term *Parapherna* (*παράφερνα*), or *Paraphernalia*, and did not become the property of the husband. All kinds of property could be the subject of *dos*. If they were things that could be estimated by number, weight, and measure (*res fungibiles*), the husband took them, subject to the liability in case of a dissolution of the marriage, of restoring things to the same number, weight, and measure. Things given as *dos* might be valued or not valued (*æstimata* and *inæstimata*); in case they were valued, the complete ownership of them passed to the husband, inasmuch as the valuation was in the nature of a sale, and the husband could dispose of the things as he pleased, subject only to the liability of restoring their value, in case of a dissolution of the marriage. If the things were not valued, and any loss ensued, without the fault or culpable neglect of the husband, the loss fell on the wife. In the case of things which were not fungibles or not valued, the ownership during the marriage might be considered as in the husband, and as returning to the wife on the dissolution of the marriage. In such a case the husband could manage the wife's property as his own; he enjoyed the profits of it during the marriage, and could sell it. With some exceptions, however, he could not sell or dispose of the wife's immoveable property which was included in the *dos* (*dotale prædium*). (Gaius, ii. § 63; *Instit.* ii., tit. 8.) The portion became the husband's on the solemnisation of the marriage, and he had the profits of it during the marriage. In the case of divorce the portion, or a part of it, according to circumstances, was restored. In case the wife died during the subsistence of a marriage, part returned to her father, and part remained to the children of the marriage, if any; but it might, by the terms of the marriage contract, become the husband's, even if there were no children of the marriage. As to the portion of the wife, whatever might have been originally the rights of the husband over it by virtue of the marriage, it was in later times the subject of the express stipulations of the marriage settlement. The questions of law which arose on the subject of the *dos* were numerous and sometimes difficult.

In enumerating the modes by which a man may acquire property *per universitatem*, Gaius mentions marriage, by which a woman comes *in manum viri*, and he observes that all things pass to the husband. The meaning of this passage is perhaps not quite certain; but it is partly explained by what has been already said.

(*Dig.* 23, tit. 3, 'De Jure Dotium'; tit. 5, 'De Fundo dotali'; Ulpian, *Frag.*, vi., 'De Dotibus'; Thibaut, *System des Pandekten-Rechts*. See Lindley's translation.)

MARRUBIUM VULGA'RE (White Horehound), a biennial or perennial herbaceous plant, common by roadsides, the officinal part of which is the leaves; these are to be collected without the stalks. They are of a whitish-gray woolly appearance, possessed of a faint odour, which becomes less by drying, and a bitter sharp taste. Ten pounds of leaves yield four pounds of extract. Their chief constituents are a bitter extractive, with a volatile oil, and probably some astringent matter.

White horehound, when young, is apt to be confounded with many other labiate plants, particularly the *Ballota nigra*, or black horehound, which possesses a disagreeable odour. The medicinal properties of horehound are very insignificant, being demulcent, slightly tonic, and astringent. As a popular remedy, it enjoys great favour in many pulmonary complaints; but the preparations vended under the name of horehound often contain more efficient ingredients, to which they owe their success, especially opiates.

MARS, the planet which comes next to the earth in order of distance from the sun, is a brilliant star, of a slightly red tint. On examination in a telescope, this colour is found to belong to parts of the surface of the planet, which have been conjectured to be land; the rest, which appears somewhat green, being supposed to be sea. Certain white spots, which appear at each pole after the winter of its hemisphere, and disappear during its summer, have been conjectured to be snow. The apparent diameter of Mars varies from 3".6 to 18".28, being 6".29 when the planet is at its mean distance from the earth. The real diameter is .517 of that of the earth, or about 4100 miles.

Its bulk is .1386 of that of the earth, and its mass is .000003927 of that of the sun, or about the 2546000th part.

The planet revolves on its axis in $24^h 39^m 21^s.3$, and the axis is inclined to the ecliptic $30^\circ 18' 10''.8$. Its light and heat are 43 per cent. of those of the earth.

Elements of the Orbit of Mars.

Epoch 1799, December 31, 12^h mean astronomical time at Seeberg.

Semimajor 1.5236923, that of the earth being assumed as the unit.

Excentricity .0933070; its secular increase (or increase in 100 years) .000090176.

Inclination of the orbit to the ecliptic $1^\circ 51' 6''.2$; its secular alteration insensible.

Longitudes from the mean equinox of the epoch (1.) of the ascending node $47^\circ 59' 38''.4$; its secular increase (combined with the precession) $2500''$; (2.) of the perihelion $332^\circ 22' 51''$; its secular increase (combined with the precession) $6582''$; (3.) of the planet (mean) $232^\circ 33' 23''.2$.

Mean sidereal motion in one mean solar day, $31' 26''.655$; in 365.4 days $689100''.739$; sidereal revolution 686.9796458 mean solar days.

MARS, or MAVORS. [ARES.]

MARSH GAS. [METHYL, Hydride of.]

MARSH'S TEST FOR ARSENIC. [ARSENIC, DETECTION OF; Marsh's Test.]

MARSHAL, a term which in its origin meant simply a groom or manager of horses; but from the importance of such an employment in a rude warlike nation, the office of marshal became invested with great military authority, which, according to the usage of the times, drew to itself a considerable civil jurisdiction. One of the principal officers of state is the king's marshal, which office is now held hereditarily by the Duke of Norfolk, who is said to have the office of marshal of England, and also an honour in respect of which he is earl marshal. This office was executed in time of war in the king's host, or army; in time of peace, in the aula regis, or king's great court. Upon the division of the aula regis, the marshal appointed deputies in the new courts. In the King's Bench the marshal's deputy was called the marshal of the marshalsea of the king's court, or marshal of the King's Bench. In the Exchequer, the deputy was marshal of the Exchequer, or clerk of the marshalsea of the Exchequer. The duty of the acting marshal is regularly to attend the court, and to take into his custody all persons committed to his custody by the court.

The lord high constable, when there was one, and the earl marshal, were the judges before whom the court of chivalry or court martial was held. This court had cognisance of contracts touching deeds of arms and of war arising out of the realm, and of all appeals [APPEAL] of offences committed out of the realm, and of matters within the realm relating to war, in cases which the courts of common law were incompetent to decide. Its proceedings were according to the course of the Roman or civil law. The earl marshal cannot hold this court alone, and there has been no hereditary or permanent high constable since the forfeiture of the Duke of Buckingham—"poor Edward Bohun"—in the time of Henry VIII. In the few cases in which the court of chivalry has been since held, a high constable has been appointed for the occasion. In the case of an appeal of death brought in 1583 against Sir Francis Drake by the heir of one Doughtie, whose head Drake had struck off in parts beyond sea, Queen Elizabeth refused to appoint a high constable; and thus, says Lord Coke, the appeal slept. The minor duties of the earl marshal are set out with great minuteness of details in a document preserved in Spelman's 'Glossary.'

MARSHALSEA. In the marshalsea of the king's household there were two courts of record. 1. The original court of the marshalsea was to hear and determine causes between the servants of the king's household and others within the verge; that is, within a circle of twelve miles round the king's palace. 2. The palace court was erected by Charles I., confirmed by Charles II., and had authority to try all personal actions between party and party, though neither of them were of the king's household, provided the cause of action arose within twelve miles round Whitehall.

The court of the marshalsea and the palace court were abolished by the statute 12 & 13 Vict. c. 101, as was also the old Marshalsea prison. (Blackstone's *Comm.*, vol. iii., R. M. Kerr's edit.)

MARSHES are those places of greater or less extent on the earth's surface, where the soil is almost constantly soaked with water. The swamp, the bog, the fen, and the morass, are so many different names for the same thing, or modifications which have not yet been defined. Whether marshes be considered with regard to their advantages or disadvantages, they are equally interesting, and are objects that call for the attention of individuals and sometimes of states. The advantages which they offer are of limited extent, and may be divided into spontaneous and artificial. The former consist in the natural productions which are furnished by some of them, of which peat is unquestionably the most important. (Ireland, Holland.) [Bog, in NAT. HIST. DIV.] Some furnish iron-ore in considerable quantity—bog iron-ore—which is formed in them by the action of decomposing vegetable matter on water holding salts of iron in solution, arising from the decomposition of other iron ores; and, though generally of a bad

kind, owing to the phosphorus it contains, it is sometimes very good, and worked with advantage (Siberia); others supply aquatic game in abundance, which is a great resource to the neighbouring inhabitants, either for consumption or as an article of commerce (the marshes of Tuscany); others again abound in eels and other fish; and some, as those of the Saône in France, and those of Poland, the Ukraine, and Bohemia, are valuable for the myriads of leeches which they furnish, and which are sent to distant parts. The soil itself, dug up from the marshes, which is called bog-earth, and the upper surface of the peat bogs, burnt or unburnt, are in many cases considered an excellent manure, and employed as such. (Poland, France.) The reeds, rushes, willows, &c., which grow so abundantly in certain marshy lands, are in many places objects of considerable importance. (Italy, Holland.) The artificial advantages to which marshes may be turned are confined chiefly to the cultivation of rice, where climate and other circumstances are favourable to the growth of this grain. (North America, Hungary.) The disadvantages of marshes are great: they are in general fatal to health, and agriculture suffers by the loss of all the marshy land. That health is materially injured by the pestilential air of marshes is evident from the fact that the ordinary mean length of life in their neighbourhood is very low. Cattle are also great sufferers from the influence of marshy grounds. The engineer Rauch says, "Marshes are the ulcers of the earth, which blur the fair face of nature, where all should be beauty; and from these infectious sores the languor of death extends far and wide over all that should live and flourish;" but the details of their baleful influence are nowhere more strikingly set forth than in the prize essay on this subject, by M. Ramel, of Paris.

A particular case, on a part of the Italian coast, derived however from another authority, will well illustrate this subject, so far as regards maritime marshes. Both ancient and modern authors have announced the fatal effects produced in the neighbourhood of marshes by the admixture of their waters with that of the sea, and a local belief of the same thing is very common and strong on the borders of the Mediterranean in Italy. On the south of the Ligurian Apennines is a marshy shore, bounded on the west for twelve miles by that sea, on the south by the river Serchio, and on the north by the Frigido, a torrent commencing at the foot of the mountains, in the state of Massa di Carrara, running three or four miles over the land, and then falling into the sea. The plain is from two to four miles wide, and is traversed by a few short streams, two of which divide it into three separate basins. The rain and spring waters which flow into these are slowly discharged into the sea by natural or artificial canals, penetrating the sand-banks on the sea-side. The level of these stagnant waters is between the levels of high and low tide in the sea, there being but little difference between these two points in this part of the Mediterranean. In this state of things, when the waters of the sea arose from any circumstance (unless the waters of the marshes were very high), they used to return up the ditches, fill the basins, and inundate the country to the foot of the mountains; and with a north-west wind, the waves used to penetrate with force to the interior. The mixture of fresh and salt-water thus formed, and which in summer was rarely changed, became corrupt, and spread infection of the most destructive kind over the neighbourhood. In this way the effects of the malaria were reproduced annually; the population, though small, presented feeble infants and diseased men, old age being unknown there. All attempts to avoid the scourge by living on the hills, or in the interior, and frequenting the plain only when the business of cultivation required, were vain; the inhabitants fell victims to the extensive influence, and much more rapidly did a stranger suffer from the deleterious atmosphere: a sojourn for one single night, in the months of August and September, causing inevitable death to the incautious traveller.

Such had been the state of things from time immemorial until 1740-1741, when, after the necessity of excluding the sea from these marshes had been insisted upon by many experienced persons, a sluice, with folding gates, competent to give emission to the waters of the marsh, but prevent the sea from entering, was constructed at the mouth of the Burlamacca. The most complete and unexpected success immediately followed upon and continued with this work. The year after its completion there were no appearances of the terrible maladies which previously appeared every year. The inhabitants soon recovered health, and the land being very fertile, the population rapidly increased. But the neighbouring parts were long left a prey to the destroying influence of the mixed marsh-waters. The 19th century had been some years entered upon before the inhabitants around other basins were considered; and it was not until so late a period as 1821, that the guarding with sluices of the remaining outlets from the marshes was complete. "Since that time," says Sig. G. Giorgini, whose account of these proceedings is here abridged, "the diseases of malaria have ceased so entirely at all points, that no other dangers are now incurred regarding the insalubrity of the atmosphere, than such as may arise from neglect of these sluices, which the inhabitants of the country should regard as their palladium." 'Ann. de Chim. et de Phys.,' 1825, vol. xxix., pp. 225-240.

The causes of the malarious condition of the atmosphere occasioned by the mingling of the marsh-waters with those of the sea, constitute too extensive a subject of investigation to be entered upon at any length in this place. It may be stated, however, that by the mutual

re-action upon each other of the sulphates contained in the sea-water, and the vegetable matter partly suspended and partly dissolved in the water of the marshes, sulphuretted hydrogen gas is copiously evolved, which if not wholly identical with the deadly miasma, certainly forms a considerable and probably the most active part of it. Further information on this subject will be found in the article SEA, where its gaseous constituents and its particular nature on certain coasts are described.

Nevertheless all marshes are not equally prejudicial to health; but independent of their different degrees of insalubrity, they present other distinguishing features. The climate, the nature of the soil, and the vegetation, are all so many circumstances which vary the appearance and character of marshes. The quantity of water is also very different; in some cases it is hardly visible, while in others, at least in certain seasons, the marsh presents the aspect of a multitude of stagnant pools covered with aquatic birds. One of the five natural orders of birds, the Waders (*Grallæ* of Linnaeus, *Grallatores* of Illiger and of Vigors) [BIRDS, in NAT. HIST. DIV.], are the characteristic feathered inhabitants of swamps and marshes; in addition to which their waters support their contingent of the order Swimming Birds, *Anseres* or *Natatores*, some of which are peculiar to them. This is the case with many of the Tuscan marshes, which are moreover remarkable for their floating islands, which sometimes unite and cover a large surface: these islands have little solidity, and, eventually sinking, become in time converted into peat, like those in the lakes of Cashmere; some of these marshes gain in extent, while the soil of others gradually rises, and the marsh disappears. Reeds are particularly abundant in the Tuscan marshes, and they are applied to a great number of useful purposes. The quality of the marsh-water also differs: thus, in some of the marshes of South Carolina, in the United States, it is salt, as likewise at Rochelle, Rochfort, &c., in France. In other places it is sulphurous, as is the case with the marshes of Mesopotamia; in many it is ferruginous, as in Siberia, where the marshes are strongly impregnated with sulphate of iron from the vitriolic springs which flow into them. The trees which are found imbedded in these marshes are so thoroughly impregnated with oxide of iron, that they supply an ore of excellent quality, furnishing a metal free from the defect of brittleness so common to the iron of most other bog-ores. In some cases the water of the marsh exhales an intolerable smell of sulphuretted hydrogen, arising from the decomposition of the sulphate of magnesia, or Epsom salts (which is continually forming on their banks), in conformity with phenomena already noticed. (Siberia, and the banks of the Euphrates.)

In cold countries marshes freeze, but seldom become dry; in warm countries, on the contrary, the marshes are often dry, and such can never form peat. As to the vegetation of marshes, it is either composed of reeds, rushes, algæ, gramineæ, or mosses, of which several species of *Sphagnum*, or bog-moss, are the most common in peat-bogs. Brushwood of various kinds, and willows and alders, are also common in marshy grounds.

Marshes are found in all kinds of situations, in continents and in islands (Iceland, Anau, &c.), on the margin of the sea, as well as in the interior of the land, on the slopes and even on the summits of mountains, as well as in the plains. Most countries have them in greater or less abundance, but it has been remarked that they are less common in Asia and in Africa (as far as the latter is known) than in Europe, and that they are more abundant in America than elsewhere. In this latter part of the world almost all the plains are wet and abound in marshes; they are exceedingly common in the northern countries of the globe, particularly in the flat parts bordering on the sea, where the land is low and the subsoil clay. Here the rain and snow-water accumulate, and remain for want of sufficient evaporation to carry them off.

It would be impossible to enumerate all the existing marshes: we may however observe that in Italy there are the Tuscan and the celebrated Pontine marshes, which are of great extent; in France there are about 1,500,000 arpens, or French acres, of marshes, some of great surface, as that of Montoire near the mouth of the Loire, which has been worked for its peat for upwards of five hundred years, and gives constant employment to 8000 persons. Ireland contains about 3,000,000 acres of marsh; the marsh or bog of Allen alone contains 300,000 acres, and there are others very extensive. England has had many marshes, particularly in Lincolnshire, Somersetshire, Kent, and Cambridgeshire; Chester, Huntingdonshire, Lancashire, and Stafford have also had extensive marshes, some of which contain embedded trees, but the improvements in drainage of modern times have rendered them insignificant, except in a few maritime localities. Scotland is much diversified with marshy ground, as in Peeblesshire, Ayrshire, Stirlingshire, Kinross, &c. As for Holland, the whole country is properly a drained marsh, and it still contains some extensive bogs which furnish peat. All the space along the coast from Holland to Denmark is little better than a succession of marsh and sand. Russia in Europe has marshes of vast extent, as those at the source of the Don, along the river Pripitz, and round the sea of Azoff, as also in Finland and the Baltic Provinces, in Lithuania and Poland. The eastern part of Prussia abounds in swamps. Norway and Sweden have some bogs, but little in proportion to their territory. In Bessarabia in Turkey, and all along the lower Danube, there are

extensive marshes covered with reeds. In Hungary the marshes are estimated at 2,000,000 arpens. Switzerland has some considerable swampy patches, many of which are on the slopes of the mountains and in the higher valleys. In Spain and Portugal there are some extensive marshes; indeed they are more or less scattered all over Europe.

Asia has its marshes and swamps, but they are less common than in Europe, if we except the northern portion, where they are in great number and very extensive, as between the lower Ob and the Yenisei, and between this last river and the Lena. There is between the little Tanguska and the Yenisei the marsh called Lis, equal in extent to the great lake Ladoga, suspended as it were in the midst of rocky hills. The province of Okhotsk has many swampy forests. A large part of China is naturally swampy, but it is to a great extent drained by the numerous canals which intersect the country. Tonquin has many marshes, and the peninsula of Malacca contains many of great extent. In India, the province of Oude has some extensive marshes covered with reeds, the retreat of great herds of wild buffaloes. The mouths of the greater part of the rivers of India are marshy, and large swamps are sometimes found along their course, as is the case with the Padder. There is a vast marsh in the valley of Cashmere, between the city of that name and the Wulur lake, from which indeed it is only vaguely separated. In the northern provinces there are many savannahs, or wet meadows. There are swamps along the Euphrates; and those of Mesopotamia are bitter, sulphurous, and salt. In Persia the province of Ghilan, in other respects fertile and beautiful, is very unwholesome on account of its marshes and marshy forests. Mazenderan has also many swamps. The eastern side of the lake Aral is marshy. The steppes of the Kirghis abound in salt marshes and pools. The Asiatic islands, that is, all those that are of any extent, contain marshes: thus part of the coast of Sumatra is covered with extensive marshes, which have caused it to receive the name of "the pestiferous coast;" the reeds are gigantic bamboos, and a continual fog hangs over the aquatic soil. Batavia, Samarang, and other places in the island of Java are reputed to be so unwholesome, in consequence of the stagnant waters and pestilential marshes, that the island has been named the grave of Europeans. The Philippine Islands have a great many peat bogs. Australia has much marshy ground along the coast, and immense swamps have been seen inland.

As for Africa, its interior is too little known to enable us to speak with any certainty of its marshes; but the southern part, according to Barrow, has many and extensive swamps covered with reeds and saline plants. Some of the rivers on the east are marshy at their embouchures, which is also the case with the Quorra. Madagascar contains marshes, in which the singular Ravenala (*Urania speciosa*), a kind of palm, grows, remarkable for the size and disposition of its leaves, which are similar to those of the banana, and are employed by the natives as table-cloths, napkins, plates, dishes, and spoons.

America contains immense marshes. In the frigid zone of the New World, as far as known, fog-enveloped marshes have been found. To the westward, in Russian America, the land lying between the coast and the mountains is a slip of black swampy soil; some of the marshy grounds are on the slopes of the mountains and retain the water like a sponge; the verdure (being covered with moss of various kinds) gives them the appearance of firm land, but in endeavouring to pass them the traveller sinks up to the waist. On the opposite or east coast of America we find Newfoundland intersected by marshes and morasses. Lower Canada has neither marshes nor stagnant water. To the south of the great lakes of North America, and as far south as Mexico, the United States contain a great number of marshes, and some of them of great extent. The low lands of Mexico also contain many swamps. The former intendencia of Vera Cruz is principally occupied with marshes and sands. South America contains a great abundance of extensive marshes, as on the upper Apure, an affluent of the Orinoco; and the delta of the latter river is one vast swamp. The region which extends between the Andes and the Pacific has little marshy ground, if we except Chaco, where there are many swampy valleys; but on the other hand the immense plains which occupy the whole interior of the continent, from the mountains of Caracas on the north to the Straits of Magalhaens on the south, contain a great number of extensive marshes. All the immense basin of the Amazon is covered with swamps and wet land and marshy forests, many of which, however, at certain seasons, form the bed of the enlarged rivers. To the south of the Campos Parexis, the provinces of Moxos and Chiquitos contain extensive marshes; in the latter particularly there is the great lake or marsh of Xarayes. This marsh is temporary, however, being dry a great part of the year, and then covered with the corn-flag (*Gladiolus*) and other *Irideæ*. In the province of Cordova are the swamp of Los Porongos, the Mar-chiquito, &c. In La Plata there is the great marsh of Ybera, formed by the infiltrations of the Parana. At the north-west extremity of the Pampa of Buenos Ayres is the great reedy marsh called Los Canaverales, and along the whole course of the Rio Mendoza, and between that river and the foot of the Cordilleras, there are extensive marshes. They also exist on the upper part of Rio Negro. In short, we may say that all the immense region of the Pampas, or plains of South America, contains marshes. In ascending the coast we find the great island of Marajo at the embouchure of the Amazons, a considerable tract of which is a marsh, formed in part by the deposit from the water of the river, and in part by the

sands of the sea. Farther north again the whole coast of French Guyana is a swamp.

This enumeration of the known marshes and swamps, though comprehensive, is however far from being complete. Very large portions of the earth's surface still remain unexplored. Nevertheless it is certain that the extent of marshy ground is very great; and probably it was formerly much greater, for a multitude of natural circumstances have greatly diminished marshes, and are still effacing them by degrees. On the other hand colonisation, and the consequent increase of population in the newly settled places, cause the clearing of forests and the draining of marshes to go on rapidly. There is no doubt that in proportion as the swamps are dried up the source of many diseases will be got rid of; but again, it may be doubtful whether the increased drought occasioned by so vast a reduction of evaporating surface may not engender other diseases equally fatal with those which now spring from the superabundance of swampy ground; and it is possible that even absolute sterility may result, in some cases, from imprudent drainage.

MARTELLO TOWER, a circular building of masonry, generally two stories high; the lower story is divided into chambers for the reception of stores, and the upper serves as a casemate for troops: the roofs are vaulted, and that of the upper story is shell-proof. The wall of the building terminates above in a parapet; and, on the terreplein of the roof are placed pieces of artillery, which rest on platforms of timber traversing on pivots, so that the guns are capable of being fired in any direction. The entrances are at a considerable height above the ground, and over these are machicolations. The whole work is generally surrounded by a ditch and glacis.

It is probable that the name of such works should be Mortella Towers, since it is supposed to have been derived from that of a fort in Mortella (Myrtle) Bay, Corsica, which after a gallant resistance was taken in 1794 by a British naval force. Many such towers were, during the late revolutionary war and since, built on the coasts of this country, in Ireland, in Jersey, and elsewhere. In England, after a period of disuse, many of these towers have recently been supplied with an improved armament.

MARTIAL ETHIOPS, the obsolete name for magnetic oxide of iron. [METALS: *Iron*.]

MARTIAL and MILITARY LAW do not mean the same thing; and though they are here joined for convenience, our observations shall be made upon each severally, without confounding it with the other.

Martial law, better known to some as drum-head law, is the arbitrary exercise of military power and authority for the purpose of enforcing complete submission, and is exerted, in the way of war, to whatever degree it be necessary, in quelling disturbance, dispersing mobs, repressing all signs of resistance, and punishing summarily on the spot any act of insubordination. It depends entirely on the will of the officer in chief command; who usually does, however, delegate this arbitrary power to a court-martial, composed of officers on the spot to judge of offences and to award punishment; and this is sometimes called a drum-head court-martial. It is this bitter kind of government, the most awful known in any state of civilised society, that the illustrious Duke of Wellington, upon an occasion still remembered in the House of Lords, when the present Earl Grey had made an inconsiderate appeal to the example of the distinguished soldier, deprecated being thought capable of ever applying to any civil community, except under modifications so extraordinary that one would scarcely have deemed the illustrious warrior's régime correctly entitled martial law. (Hans. Deb., 1 Apr. 1851.) By the Riot Act, the imperial parliament of this country has enabled the civil magistrate, when municipal authority is for the time set at defiance, and no longer avails to preserve the peace, to call out the military, and to give the commanding officer authority to disperse the people by force. The unfortunate condition of Ireland has frequently occasioned the express intervention of parliament to suppress insubordination by this kind of authority; and the lawless state of the people, evinced by agrarian outrages, and the perpetration and subsequent concealment of murder, under circumstances which demonstrated a cruel conspiracy of many and a general approval of the deed, has too often required the enforcement of a general Act, which enables the lord lieutenant to proclaim any district stained by such crimes and to place it under the surveillance of armed police, in greatly increased numbers, with greatly increased powers. These, however, are very modified instances of the application of martial law.

Military law, sometimes confounded with the other, is now in this country a well-known code of discipline applicable to her Majesty's land forces and marines, both in times of peace and war. It emanates necessarily from the authority of all laws in this country—the civil power. It is applicable only to the regular forces, unless by Act of Parliament the militia and volunteer forces, when enrolled, are placed under it. Civilians are amenable to the municipal law and no other, and any one who inflicts upon such a person in this country not *in statu pupillari* any punishment whatsoever except by authority of that law and the civil magistrate, is answerable for his conduct in a court of justice, civilly to the sufferer for the wrong done him, and criminally to the sovereign for the public offence.

This distinction between the two classes of persons with respect to

military law is clearly expressed in the "Mutiny Act," as it is called, which was first passed in the reign of William III. After stating that the subjects of this realm cannot be punished in any other manner than conformably to the common laws of the country, an exception is immediately enacted in the case of military persons; and then follow several provisions for the purpose of bringing soldiers who shall mutiny, excite sedition, or desert from the service, to a more exemplary and speedy punishment than the usual forms of law will allow.

Immediately after the Norman conquest of this country the military law consisted in the obligation imposed on the vassals of the crown to follow the king to the field, under penalty of a pecuniary fine or the forfeiture of their land. But the first known record concerning the regulation of the army is believed to be that which was made in the reign of John; and this relates chiefly to the purchase of provisions at the sales held for supplying the army with necessities. The ordinances of Richard II. and of Henry V., and the statutes of Henry VIII., contain many useful rules for the government and discipline of the army. They prescribe obedience to the king and the commanders; they award punishments for gaming, theft, and other crimes; for raising false alarms in the camp, and for the seizure of religious persons. They also contain regulations concerning the disposal of prisoners taken in battle, and concerning the stakes, fascines, ladders, and other materials for military operations, with which the soldiers were to provide themselves. (Grose, 'Mil. Ant.' vol. ii.)

The early kings of this country do not appear to have exercised, generally, a discretionary power over the army; for a statute of Edward I. states that the king had power to punish soldiers only according to the laws of the realm. The court of high constable and high marshal of England had for many years an exclusive jurisdiction in all military affairs, and this was sometimes extended over the civil courts. But the power of that court was restrained by a statute in the reign of Richard II. (1386); and the court itself, with the whole feudal system on which it was engrafted, gradually fell into disuse, and was displaced by an order of things with which it had little in common. No one however can point to the time that exactly divides the two eras. An interval occurred when it would have been difficult to say what was abiding. All was in a state of change: old things were passing away, and all things were becoming new. Charles I. was so unfortunate as not to discern the signs of the time. He placed himself in the breach, and hoped alone to stem the tide of progress; and there was a romantic chivalry in men's hearts which induced many to join him. They were borne down, and the genius of a great military system arose in Oliver Cromwell. The man himself was discipline; he made his soldiers, and they made him. The Stuarts returned with the Restoration. The army of 5000 men which Charles II., contrary to the constitution, maintained constantly in this country, became under his successor a body of 30,000 troops, arbitrarily levied, and therefore with difficulty retained to their standards on Hounslow Heath. Desertions became rife: pettier acts of insubordination were of course committed. The civil law knew no authority which could retain a man in the ranks against his will; and if he beat his officers, they might indict him for assault and battery, and the jury might refuse to convict. The celebrated Lord Holt, afterwards Chief Justice, was then Recorder of London. He maintained the law of England against the authority of James, who wished to enforce a discipline that rested entirely on his own sanction. Even Chief Justice Herbert found the demand of his sovereign too great for him, and he also maintained the civil law. Readier instruments were therefore found for the bench in London and at Westminster; arbitrary sentences followed; and death penalties and severe punishments astounded all the country, although applied to the army. The revolution at length succeeded this state of things, under the discernment of statesmen who knew the times were altered, and provided for them in accordance with the constitutional law of the country.

MARTLET. [HERALDRY.]

MARTYRS, MARTYROLOGY, from the Greek *Martur* or *Martus* (*μαρτυρ* or *μαρτυς*), a witness.

By the term *martyr* we now generally understand a person who suffers death rather than renounce his religious opinions; and those who have made a profession of their faith and thereby endured sufferings short of death, are called *confessors*. These terms appear to have been used in the same sense by some of the early Christian writers; but others give the title of *martyr* to all who suffered tortures on account of their faith, and that of *confessor* to those who were only imprisoned for its avowal. Tertullian calls the latter "*martyres designati*," *martyrs elect*. The annals of the early Christian church contain the histories of many martyrs, whose astonishing fortitude under the most cruel tortures was doubtless one great cause of the rapid diffusion of Christianity. Among the earliest and most valuable documents relating to this subject are the letter of the church at Smyrna, giving an account of the martyrdom of Polycarp (A.D. 167), and that of the church at Lyon and Vienne, (A.D. 177), concerning the martyrs who suffered in the same reign, namely, that of Marcus

Aurelius Antoninus. (Eusebius, 'Ecc. Hist.' iv. 5; v. i.; and Lardner's 'Works,' vol. vii., p. 150, edition of 1831.) The histories of these martyrs are called Martyrologies, of which the earliest is that of Clement I., bishop of Rome. Middleton has shown that many of the accounts in the early Martyrologies are fabulous. He mentions, in his 'Letter from Rome,' some curious instances in which persons who never existed, heathen deities with their names slightly or not at all changed, and even inanimate objects, have been canonised as saints and martyrs. As examples of this description of works we may mention the 'Martyrology' of Eusebius, which was translated into Latin by Jerome, and was celebrated in the early church, but is lost; that ascribed to the venerable Bede, but the genuineness of which is very doubtful; and the 'Acts and Monuments' of Fox, which is an elaborate and valuable record of the sufferings of the English reformers.

Much interesting information on this subject may be found in Ruinart's *Acta Martyrum*; Dodwell's *Dissertationes Cyprianicæ*, v., xi., xii., xiii., and Dr. Conyers Middleton's *Free Enquiry into the Miraculous Powers supposed to have subsisted in the Christian Church*.

MASCAGNIN ($\text{NH}_4\text{O}, \text{SO}_3 + 2\text{aq.}$), volcanic sulphate of ammonia, occurs stalactitic and pulverulent. Colour yellowish or grayish; taste acrid and bitter; translucent or opaque. Volatilised entirely at a high temperature. Occurs among the lavas of Etna and Vesuvius, &c.

MASCULINE and NEUTER. [GENDER.]

MASONRY (from the French word *maçonnerie*), signifies the application of stone to building purposes. It is a most important branch of the arts of construction; because much both of the beauty and durability of an edifice depends upon the excellence of the workmanship, and upon the colour and resistance of the stone. In situations where the geological character of the soil is clayey, or where stone is only to be obtained by means of a long and expensive land carriage, there is so important an economical advantage in the use of bricks, that stone is rarely resorted to, unless it be for the external decoration of important public buildings; and much of the style and taste of any particular locality may be attributed to the relative abundance of these materials, or rather, to the nature of the materials employed to produce the external effect of a building. Thus we find that in the greater part of England, and in Holland, where stone is only used exceptionally for elevations, and where brickwork is the normal mode of building, there is generally an absence of bold, and what may be called palatial, character in the prevalent style of architecture; whilst in Edinburgh, Paris, Genoa, Rome, Madrid, &c., the stone elevations of the houses and public buildings are marked by a breadth of handling our London architects rarely attain. Perhaps the great facilities for internal communication afforded by the railway system, may bring about a change in the style of construction adopted in London; but the facts of the co-relation between the habitual use of stone and the state of architectural taste, and of the influence which that material exercises on architecture, will remain the same.

Stone is used in walling, either in what is called rubble, or in ashlar masonry; or sometimes again in the style called brick and stone, or mixed masonry. Rubble masonry, in its turn, may be either random or dressed, according as the separate stones are dressed, or are left in the rough state in which they leave the quarry. Ashlar work is usually, but not necessarily, executed with large stones, which, under all conditions of size at least, are dressed to regular faces on the beds and joints; whilst the exposed faces may either be left rough, or they may be worked to a smooth surface. In mixed masonry the proportions of stone and brick vary greatly; for in some instances the use of stone is confined to the window-dressings, strings, cornices, &c., and in others it is further introduced in bonding courses, or alternate layers. Another technical subclassification of walling masonry is derived from the manner in which the faces of the stones are dressed; and according to the nature of the material: it is said, if granite be used, to be polished, fine gritted, fine axed, bolstered, or point dressed; if limestone be used, it is said to be rubbed, tooled, or hammer-dressed; and the same words apply to sand stones. In some styles of architecture an attempt is made to secure a certain amount of picturesque effect, by treating the surface of the stone in a bold, but affected, style of rough dressing, known amongst architects by the name of rustications, or of vermiculations. In these remarks upon the use of stone, attention has been only directed to walling purposes; because its application to window and door cills, to lintels, copings, staircases landings, paving, &c., is rendered so compulsory by the very nature of the requirements of the particular cases, that the discussion of the conditions of those branches of the mason's art must be left to the particular subjects themselves.

The qualities to be sought for in a building stone are durability, facility of working, capability of receiving a fine surface, and agreeable colour; but, as in all large towns, the state of the atmosphere is to a greater or less extent able rapidly to modify the original colour of the stone, the conditions of durability, and of the facility of working, in so far as the latter is likely to affect the cost of the work, are the most important. It would appear that there is some hitherto unexplained law affecting these questions, whereby the stone of any particular locality resists the atmospheric influences of that locality more successfully than it could do those of any other situation; but whatever may be the explanation of this phenomenon, it is certain that an atmosphere highly charged with carbonic, or with sulphuric, acid gases, is highly

dangerous to the building stones usually employed. It is on this account that London and Manchester are so particularly unfavourable for masonry, and require such extraordinary care in the selection of the stones intended to be used in the elevations of public buildings in them, even without reference to the normal conditions of decay. As the atmosphere of every town has its own distinctive peculiarities, it may be as well to illustrate the above remarks by some incidental references to the action of the London atmosphere on the stones hitherto exposed to it; and to accompany them with some other incidental remarks on the accidental circumstances likely to modify the general laws thus arrived at. [ATMOSPHERIC INFLUENCE.]

The stone which hitherto has been proved to be the most adapted to resist the action of the London atmosphere is the Portland oolite: a fine-grained, sub-crystalline, carbonate of lime, of considerable hardness and density, and without any very distinct traces of bedding in the best varieties. The cost of the labour upon it, and the high price of the stone itself, on account of the limited source of supply, render the use of Portland stone less common than would be desirable, and have led to the introduction into the London stone market of cheaper and inferior materials. There are, however, some outlying patches of the Portland oolite which might be brought to London at the present day, such as the Tisbury, Upway, and Purbeck deposits; and it really seems that the fault of the high price of this variety of stone lies rather in the want of enterprise on the part of the merchants, than in any scarcity of the raw material. Portland stone, like all regularly stratified bodies, cleaves more easily in one direction than in others; but in the finer beds (that is to say, in the beds producing the finest stone) the character of the molecular structure becomes so homogeneous that the planes of stratification become imperceptible; and when this is the case there is less danger in using the stone, for ordinary purposes of masonry, in false bedding, than would be the case if the planes of separation of the beds were more distinctly marked. The best beds of the Portland stone are exposed to the inconveniences of flint nodules, and of vents, as the workmen call the cracks produced in the mass of the stone by the contractions which accompany its solidification. The upper beds, or the roach Portland, are shelly, more decidedly crystalline in the structure of the cementing material around the fossils, harder and more difficult to work, and totally unfit, on account of the numerous holes of the fossils, to be used in the masonry of ornamental structures; whilst, for hydraulic works, or other purposes requiring great strength and durability, the roach is of great value.

The member of the oolitic series which has supported the action of the London atmosphere the most successfully, after the Portland stone, is the material known as the Kelton stone, obtained from the midland counties; and, like the Painswick variety of the same formation which also stands tolerably well in London, it appears to owe this property to the more decided character of the crystallisation of the molecules of the cementing materials of the oolites. The Bath stone, when very carefully selected, and used with all necessary precautions as to bedding, and removal from excessive moisture, resists tolerably well; but the general character of the deposit is too irregular, and the habits of London masons are too careless in everything which regards the use of building stones, to allow either the Bath stone, or the analogous member of the great oolite obtained from Caen in Normandy, to be employed for external masonry in the metropolis. The Barnack stone, formerly used to a great extent in Lincolnshire, Cambridgeshire, and the Isle of Ely, has been exhausted, and its place is now locally supplied by the Casterton stone; these local varieties of the oolite are characterised by an abundance of minute fossils, corals, and foraminifera, and when well selected they seem to be tolerably durable. But it may be observed with respect to them, and to the Ancaster stone (a very beautiful looking material, said to be used successfully in the midland counties), that until they have been employed for a long time in the peculiar atmosphere of London, it would be dangerous to pass an opinion upon their merits.

There are several descriptions of sandstones used in London, and in various parts of England, for walling or external masonry, such as the Dundee and Arbroath stones, those from Cragleith, Darley Dale, Park Spring, and the neighbourhood of Leeds and Halifax; but neither on the score of their colour, or of their durability, can they be considered to be superior to the Portland stone. For some uses, as for steps, door cills, paving, hearths, &c., the Yorkshire and Arbroath stones present advantages on the score of their great strength, hardness, and ease of conversion in the direction of the bed, and also on account of their power of absorption of moisture, which renders their use desirable for all masonry works in the interior of dwelling houses. These sandstones when used in elevation are, however, exposed to decay "between wind and water," as the masons designate the zones of walls exposed to alternations of dryness or humidity. Unfortunately the magnesian limestones, lately introduced for the construction of the Houses of Parliament, have decayed in these positions even more rapidly than the worst sandstones formerly employed; and it is no exaggeration to say that the actual state of the masonry of that building has assumed the proportions of a national misfortune. The Kentish rag, so much used for the rubble filling between the dressed quoins of mediæval architecture, in the modern revival of that style, appears to resist the action of the atmosphere very well; but it is unfortunate that in these buildings the material used for the quoins is generally

selected from the softest and most perishable stones. The conditions under which the siliceous conglomerates, such as the Bramley Fall, or the trap, basaltic, and granitic rocks decay, and which therefore must regulate their application for purposes of masonry, have already been discussed. [ATMOSPHERIC INFLUENCE.]

It follows from these observations upon the decay of stones that they require to be used with precaution, even when of good quality. Care should be taken to lay them in true bedding; the softer and more absorbent stones should not be used in the lower parts of a wall, or in situations where they would be likely to take up moisture from the ground, or from any projections of the ornamental masonry, by capillary action; and the use of limes, cements, or plasters, able to give rise to an efflorescence of the salts in the stones, must be avoided. There have lately been introduced some processes for the induration and preservation of building stones, the best of which seems at present to be Ransome's process, notwithstanding the adverse opinion of Faraday; but in fact every method for obviating the decay of a bad stone can be only a palliation, more or less perfect, for an original defect; and the common sense of this matter is to use originally a stone which should be able from its own constitution to resist the conditions to which it is likely to be exposed, rather than to attempt to remedy its defects. Highly ornamental masonry executed in soft stone may be, however, protected by the application of such processes as those above named; but they should only be regarded as hazardous and temporary methods of obviating present dangers, especially as their success must essentially depend on the care and skill with which they are applied.

In the execution of masonry, such as we generally see in the south of England, where the face is usually executed in ashlar of a less thickness than the wall, the ashlar is backed up with brickwork, which should be set in cement, in order to prevent any inconvenience from the unequal compression of the respective materials. Great care is also required in the execution of mixed masonry to obviate danger from the same cause; because the vertical chains of stone-work do not compress at the same rate as the filling-in brick-work, unless the latter be executed with a cementing material able to solidify in a very short space of time. The longitudinal courses of mixed masonry, as a general rule, run through the wall; or if this should not be the case the outer ranges of stones are connected with the mass of the work by means of bond stones, a system of construction equally applied to ashlar work backed up with brick. In other respects the rules for the execution of masonry are identical with those of brickwork; that is to say, the vertical joints in elevation should never be placed immediately over one another, nor should the facing work be distinct from the backing, in such manner at least as to allow any separation between the two.

Some mechanical distinctions between the various kinds of stones may here be alluded to, on account of their important influence upon the cost of masonry. Thus the granites, and the siliceous conglomerates, are not susceptible of being sawn, but can only be detached in masses by means of wedges; the sandstones, and the harder oolites, can only be sawn by means of the framed, or plate saw, and sharp gravel and water; whilst such stones as the Bath, Caen, &c., are worked by the toothed saw. The first class above-described, or the stones unable to be sawn, are worked by means of points, or axes; and in remarkably fine works they are occasionally polished: the second class is worked by the hammer, the mallet point and chisel, and sometimes "rubbed fine:" the third class, or that of the soft oolites, is worked by axes or by tools slightly resembling those used by joiners, and the finished surface is, in England, obtained by the use of "the drag"—a tool very much like a short hand-saw. Rubble masonry is usually left rough from the tool, whilst Ashlar work, especially in the decorative parts of a building, such as strings, cornices, window and door dressings, &c., is either rubbed, or brought to a smooth face by the drag: in some cases however, as in what are called rusticated courses, the stones are occasionally worked with a straight chase round the joints leaving the remainder rough from the tool. [RUSTICS.]

The above remarks have been almost exclusively applied to the manner in which masonry is executed in London; but the leading principles they involve apply equally to that art in other countries; for the mode of bonding the material, the precautions to be observed in order to avoid unequal settlements when rubble and ashlar are combined, or when cementing materials of variable powers of expansion in setting are used, and the principles to be observed in selecting the stones and in placing them in a building, must be identical in every locality. It may be interesting, however, to the student of the arts of construction, to mention that the practice of the ancients in this particular branch has been elaborately described by Vitruvius; and that the practice of the moderns of recent times may be studied in detail in such works as Rondelet's 'Art de Batir;' or in Gwilt's 'Encyclopedia of Architecture.' Practically there is no difference between the styles of masonry adopted in former times and those now used, for the various systems of bonding used by the ancients, and described by Vitruvius under the names of the *opus insertum*, *reticulatum*, *imbricatum*, or *revinctum*, the *isodomum*, *pseudisodomum*, or the *emplecton*, are, in fact, only varieties of what would at present be described as coursed rubble, or small ashlar masonry. The Egyptians seem, however, to have attached great importance to the use of stones of large dimension, and even occasionally to have executed monolithic structures of con-

siderable importance; and the taste for this peculiar element of sublimity of expression in buildings may also be said to have pervaded all the Eastern nations directly concerned in the early progress of civilisation, for it may be discovered in the monuments of Persia, Media, and in those of Tadmor and Palmyra. The character of the materials used by the Greeks (that is to say, the large straight block), which they obtained with facility from their marble rocks, had a marked influence also on the expression of their architecture, inasmuch as their masons were able to span large openings by straight beams or lintels; whereas the Romans, and, generally speaking, the inhabitants of the West of Europe, have been driven, by their lack of materials for the execution of such trabeated masonry, to resort to the use of bricks, or of small stones, used as arches for the purpose of spanning the openings so much more easily dealt with when long lintels could be obtained. The Cyclopean masonry, as the irregular rubble work executed with stones of enormous dimensions, is called, and of which antique specimens are to be seen in the countries formerly inhabited by the Pelasgic tribes, or in the modern structures of parts of Germany and of Spain, is again little else than a modification of the styles of masonry already described.

In some cases, where coloured marbles are obtained at small expense, they are applied as ornamental decorations by being let into panels in the external walls, or even in some instances they are exclusively used for the face work. Nearly all marbles are pure carbonates of lime of a highly crystalline character, and they are therefore exposed to the destructive actions before alluded to as being likely to affect the more earthy carbonates, although in an inferior degree. For internal masonry, however, marble may be used without hesitation in situations at least where the following objections would not apply; that is to say, that when used for chimney-pieces marble is exposed to a slow calcination if placed too near the fire-place, and it loses its crystalline to assume a saccharoid texture in proportion as the carbonic acid gas is driven off by the heat. The marbles, again, which contain veins of a different nature to the mass of the material, are exposed to unequal contractions, and the Italian black and gold, for instance, or the serpentine (though strictly speaking the latter can hardly be called marbles), frequently crack upon the lines of the veins. Marble is in some countries, as in Holland, much used for lining the walls, and paving entrance halls; but unless great care is taken to maintain an equable temperature, and a great degree of dryness in the atmosphere, a very unpleasant condensation of vapour takes place upon the face of the marble, in consequence of its powers of rapid conduction, and of its non-absorption. At the present day the fashion is to use foreign marbles for ornamental masonry, and the English market is supplied from Belgium and Italy; but there are some singularly beautiful materials of this description to be obtained from our own country, and their neglect must be a cause for regret to artists and to economists. Marbles are worked by the mallet and chisel, and sawn by the plate-saw; indeed, on account of their uniform character, they are susceptible of being worked by steam machinery.

MASONS, FREE. According to the extravagant and whimsical hypotheses entertained by some of those who have written upon the subject of freemasonry, it is an institution of almost incredible antiquity. We are told by some that it originated with the builders of the tower of Babel, though others are content with tracing it no farther back than the temple of Solomon. If we are to believe them, the institution has been continued down in uninterrupted succession from that very remote time to the present day, through all the changes of governments, religion, civilisation, and knowledge. Against this there exists one very simple, yet fatal, argument, namely, that were this really the case, such an uninterrupted series of tradition must have kept alive and handed down to us much information that has, on the contrary, been utterly lost. Instead of accumulated knowledge, we find that even a technical knowledge of architecture itself has not been so preserved; else how are we to account for the ignorance which everywhere prevailed with respect to Gothic architecture and its principles almost as soon as the style itself fell into disuse? That there may have been many points of resemblance between the fraternities of masons in the middle ages, and such institutions as those of the Eleusinian mysteries, and the corporation of Ionian architects, is not only possible, but highly probable, because similarity of circumstances would almost necessarily lead to it. Before the invention of printing, when the means of communicating knowledge were few and imperfect, no readier mode presented itself of extending and keeping up the speculative and practical information spread among any profession, than by establishing the profession itself into a community or order, all the members of which would have one object and one interest in common. This would be more particularly the case with regard to architecture, which calls for the co-operation of various branches of science and the mechanical arts, and was moreover for several ages the paramount art, all the other arts of decoration being, as far as they then existed, subservient to it.

The importance of architecture to the church, on account of the impressive dignity it conferred upon religious rites and the ministers of religion, naturally induced the clergy to take it under their especial protection. For a long time not only were ecclesiastics the chief patrons but almost the chief professors of the art; yet as they had occasion for the assistance of practical artificers in various branches,

they admitted them into fellowship with themselves, establishing a kind of order of a mixed character, just as the orders of chivalry combined at their origin the principles of military and religious discipline. Hence some have supposed freemasonry to have been a branch of chivalry, and to have been established at the time of the Crusades. The more probable hypothesis perhaps is that they were related to each other only in emanating from the same source—from the influence of ecclesiastical power; and their being so derived would alone account for the mystery and secrecy which the guilds of masons affected; and, together with their zeal in accumulating knowledge for themselves, their desire to confine it to their own body.

By means of these associations the inventions and improvements made in architecture were communicated from one country to another, a circumstance which at once accounts for the sudden spread of pointed or Gothic architecture throughout the whole of the west of Europe; and at the same time renders it so exceedingly difficult to determine at all satisfactorily where that style actually originated, or what nation contributed most towards its advancement. Owing also to the jealousy with which the masons kept their knowledge to themselves, it is not at all surprising that the history of the art during the middle ages should be involved in so much obscurity that it can now be traced only by its monuments, all documents relative to the study of it having been concealed as much as possible, even when something of the kind must have been in existence. Among the causes which led afterwards to the decline of these institutions was, on the one hand, the suspicion with which the church itself began to regard them as societies that might in time acquire an influence not easily watched, and which might be turned against itself; and on the other, the spread of information, together with the revival of the arts, which deprived such bodies of their utility and importance, and rendered it impossible for them to confine their knowledge exclusively within their own pale.

In this country an act was passed against Masonry in the third year of Henry VI., at the instigation of the Bishop of Winchester. It was however never enforced, and Henry himself afterwards countenanced the brethren by his presence at lodges of masons. It was also patronised by James I. of Scotland: but it was no longer indispensable to the church, which accordingly withdrew its protection—an event that would otherwise have been occasioned by the Reformation.

Freemasonry revived again in this country about the time of the civil war, yet merely in semblance, being altogether different in object and character from what it had been, and becoming merely "speculative" or modern Masonry, an institution in nowise connected with architectural practice. From this country it was first introduced into France about the year 1725; into Spain in 1728, and into Italy in 1733, when the first masonic lodge was established at Florence. It was afterwards however the object of persecution not only in France and Italy, but also in Holland and Germany. Some writers, more especially Abbé Baruel and Professor Robison, have made it a charge against freemasonry that it has been converted into an organised secret conspiracy against religion and existing governments. If the charge has been unjustly made, it must be owned that the profound mystery in which it has cloaked itself gave some colouring to such charges, it being but natural to infer that if there was anything to call for such extraordinary degree of secrecy, it could hardly be sought for good, or in accordance with the interests of society at large. The greater probability is, that there is nothing either good or bad to conceal; that the mystery of freemasonry is nothing more than an innocent mystification; and that its symbols and instructions, whatever meaning or purpose they may originally have had, are now become mere forms and signs retained by the brethren, or "free and accepted masons," as they style themselves, for the purpose of conferring peculiar importance on their harmless social meetings.

MASQUERADE from the Spanish *mascara*, (which is from the Arabic *mas-chara*, a mimic or sport-maker, Italian *mascherata*, and French *mascarade*), an amusement introduced into England in the 16th century from Italy, though the use of masks for purposes of satire is of great antiquity, and was practised by the Greeks and Romans. Hall in his 'Chronicle,' says, "On the daie of the epiphaine, at night (A.D. 1512-13), the king (Henry VIII.) with eleven others were disguised after the manner of Italie, called a maske, a thing not seen afore in England: thei were appareled in garmentes long and brode, wrought all with golde, with visers and cappes of golde; and after the banquet doon, these maskers came in with the six gentlemen disguised in silke, beryng staffe torches, and desired the ladies to daunce: some were content; and some that knew the fashion of it refused, because it was not a thing commonly seen: and after thei daunced and commoned together, as the fashion of the maskes is, thei toke their leave and departed, and so did the quene and all the ladies."

The distinction between this species of amusement and the disguisings and mummings of the middle ages appears to have been the general mingling of the company in dance and conversation, in lieu of the execution of a particular dance or preconcerted action by certain individuals for the entertainment of the guests, the latter being as old at least as the time of Edward III. in England, and the precursors of the dramatic masque of the 16th century. In "the garmentes long and brode," and "disguisings of silke," we may perceive the present *domino*, so called, according to some authorities, from an ecclesiastical

ARTS AND SCI. DIV. VOL. V.

vestment (a black hood worn by canons of cathedrals), *dominus* being a title applied to dignified clergymen in the middle ages. Others derive it from the ordinary robe or gown worn by Venetian noblemen at that period. Granacci, who died in 1543, is said to have been the inventor of masquerades: at what particular date does not appear; but from the above evidence of Hall, they had become fashionable in Italy as early as 1512. In England the disguisings are of the most fantastic variety, but the characters assumed as a disguise are seldom well sustained, and the amusement afforded is consequently of a very indifferent and often of a very equivocal kind.

MASS. By the mass of a body is meant the quantity of matter which it contains, upon the supposition that differences of weight are always the consequence of different quantities of matter. This involves an hypothesis; for instance, if gold be, bulk for bulk, nineteen times as heavy as water, it is presumed that a given bulk of gold contains nineteen times as much matter as the same bulk of water. But it is possible that if we were better acquainted with the constitution of these bodies, it might appear that we are wrong in supposing difference of quantity to be the cause of difference of density.

The fact is, that mass means weight; so that of two bodies, the heavier is that which has the more mass: why, then, is this word introduced at all? If we had only to consider bodies at the surface of the earth, we might in all cases substitute weights for masses; but when we have occasion to speak of bodies at very different distances from the centre of the earth, their weight towards the earth, which is then called the attraction of the earth, depends upon their distance from the earth, as well as their absolute constitution. If we imagine two planets at the same distance from the earth, the attractions of the earth upon the two will then be in a proportion which depends, not on that distance, but on the amount of matter in the two planets.

When we say that Jupiter has only the 1047th part of the mass of the sun, we express—1, a fact of which observation and deduction make us certain, namely, that at the same distances the attraction of the sun upon the earth is 1047 times as great as that of Jupiter upon the earth; 2, an hypothesis of the following kind, that the sun contains 1047 times as much matter as Jupiter. The hypothesis is a convenience, not affecting the truth or falsehood of results; the fact represented remains, that at the same distances the sun does 1047 times as much towards deflecting the earth as is done by Jupiter.

In the application of mechanics, the following equations frequently occur:—

$$\text{Weight} = \text{mass} \times \text{force of gravity.}$$

$$\text{Mass} = \text{volume} \times \text{density.}$$

These equations, like others of the same kind, are to be understood with tacit reference to the units employed; they spring from the following proportions:—Any two masses are to one another in the ratio compounded of that of the volumes and that of the densities; thus the two bodies being eight cubic feet three times as dense as water, and seven cubic feet four times as dense, the masses are in the proportion of 8×3 to 7×4 , or of 24 to 28. Again, if two different masses be acted upon by pressures which would, in a unit of time, create different amounts of velocity, the pressures are to one another in the ratio compounded of that of the masses and that of the velocities which would be generated in the unit of time. Thus if the preceding masses, which are as 24 to 28, were subjected to attractions which would produce in single particles velocities of 10 and 11 feet, if allowed to act uniformly for one second, the pressures requisite to prevent motion at the outset would be as 24×10 to 28×11 , or as 240 to 308.

To convert these proportions into equations, let the unit of time be one second, that of volume one cubic foot, and let water be the substance which has the unit of density; also let the unit of length be one foot. Then, if the unit of mass be one cubic foot of water, and the unit of weight the pressure necessary to restrain a unit of mass acted on by an attraction which would, in one second, give a velocity of one foot per second, the preceding equations are true. [WEIGHT; SPECIFIC GRAVITY; ACCELERATION.]

MASS (*Missa*, in Latin). The derivation of the word "missa" has been variously accounted for; some derive it from *missio* or *dimissio*, "dismissal," because in the early ages of the church the catechumeni, or new converts who were not yet admitted to partake of the sacrament, were sent out of the church after the liturgy was read, and before the consecration of the Host. Others derive it from the Hebrew word "missah," that is, oblation or sacrifice in commemoration of the sacrifice of our Redeemer for the sins of mankind. Ducange, in his 'Glossarium,' art. 'Missa,' gives the various opinions on the etymology of the word. The word *missa*, signifying the ceremony or rite of consecrating the Host, is found in the epistles of St. Ambrose, St. Augustine, and Cesarius, bishop of Arles. See also Baronius, in his 'Annals.'

The mass is a church service which forms an essential part of the ritual of both the Roman Catholic and Greek or Eastern churches, and in which the consecration of the sacramental bread and wine takes place. The *canon of the mass* now used by Roman Catholics, was first compiled by Pope Gregory the Great, and it was long before it was adopted in all the Latin churches. In the 8th century arose the practice of *solitary masses*, performed by priests alone in behalf of souls in purga-

L L

tory, but the practice was condemned by the church at a synod held at Mentz before the end of the century. This service is performed entirely by the officiating priest standing before the altar, and attended by a clerk who says the responses. The prayers of the mass are all in Latin in the Roman Catholic church, in ancient Greek in the Eastern church, and in Syriac among the Maronites and Jacobites, but never in the vulgar or vernacular tongue of the country. The congregation take no ostensible part in the service, but they follow it mentally or in their prayer-books, in which the text of the prayers is occasionally accompanied by a translation in the vulgar tongue. The priest does not address the congregation, but has his back turned to them, except at the end of certain prayers, when he turns round, and says, "Dominus vobiscum" ("The Lord be with you"), and at the "Orate Fratres," &c. ("Brethren, pray," &c.), which are responded to, on the part of the congregation, by the clerk. The mass consists of various parts:—1. The Introitus, or preparation, consisting of several prayers, psalms, the 'Gloria in excelsis,' the epistle and gospel for the day, the Creed, &c., which the priest recites with a loud voice. 2. The consecration, in which the priest consecrates the bread and wine, repeating the words, "Hoc est corpus meum, et hic est calix sanguinis mei," and then shows to the people both the bread and the chalice containing the wine, upon which all the congregation kneel down. 3. The communion. The priest, after reciting more prayers, accompanied by an invocation of the apostles and other saints, the Lord's Prayer, &c., takes the sacrament under both forms; if any of the congregation are disposed to take the sacrament, the priest then descends from the altar and administers it to them in the shape of the consecrated wafers or bread only. 4. The post-communion, which consists of a few more prayers, and of the blessing which the priest gives turning towards the congregation, after which he reads the first chapter of the gospel of St. John down to the fourteenth verse, and the mass is over.

The low or ordinary mass, *Missa brevis*, lasts in general about half an hour, and every Roman Catholic is bound, by what are styled the "Commandments of the Church," to attend it once at least on Sundays and other holidays, unless prevented by illness. The transgression of this precept is reckoned a sin. Pious persons hear several masses in succession, and many attend mass every day in the week, for it is celebrated every day in each parish church. A priest must not break his fast either by food or drink from the previous midnight until he has said mass, out of respect for the real presence of Jesus Christ in the sacrament. The service of the mass is indeed essentially connected with and depends on the doctrine of transubstantiation. [TRANSUBSTANTIATION.]

On great festivals and other solemn occasions the mass is performed by a priest or prelate, attended by a deacon and subdeacon, who says the responses and chants the epistle and gospel of the day. On those occasions the mass, or at least parts of it, are sung by a choir, accompanied by the organ and other musical instruments. This is called "high mass," and is a long and pompous service. Palestrina, Mozart, Cherubini, and other among the most celebrated musicians, have produced most beautiful compositions for this service. Both for the low and the high masses the officiating priest is dressed in peculiar various-coloured garments appropriated to the occasion, which he afterwards takes off in the vestry-room.

The 'Missale' is the name of the book which contains the ritual of the mass, and which the priest holds open before him on the altar. Some of the old Missals, whether MSS. or printed, are beautifully ornamented with paintings, and are valued as bibliographic curiosities.

The Protestant and reformed churches have no mass, as they do not believe in the doctrine of transubstantiation; but several of the detached 'Oremus,' or prayers of that service, which are very fine, have been retained in the Liturgy of the Church of England, translated in the vulgar tongue.

MASSA'GETÆ, an ancient people of central Asia, in an expedition against whom Cyrus is said to have lost his life. ('Herod., i. 205-216; 'Justin., i. 8.) Alexander also met them in his expedition to Sogdiana, B.C. 328. ('Arrian,' iv.) Herodotus says that they lived north of the Araxes, by which he probably means the Jaxartes (i. 201), and on the plain to the east of the Caspian Sea: this would include the country now known as Sungaria and Mongolia, extending to the base of the Altai mountains. According to Strabo, the Hyperborei, Sauromatæ, and Arimaspi dwelt above the Euxine, the Ister, and the Adriatic; and the Sacæ and Massagetæ above the Caspian (p. 507, Casaubon); and a little further he remarks that the Massagetæ were to the east of the Dææ, who bordered on the Caspian Sea (p. 511).

Herodotus was in doubt whether the Massagetæ ought to be reckoned among the Scythians (i. 201); but they were usually regarded as part of the Scythian nation by succeeding writers. ('Arrian,' iv. 17; 'Pliny,' H.N., vi. 19.) Strabo (xi.) details some of the inhuman customs of the tribe; which lead Niebuhr and Birkh to consider the Massagetæ as a branch of the Mongolian race; while Humboldt ('Central Asia') believes them to have been of the Indo-European stock. The similarity of their name (*Massa-getæ*; compare *Tyri-getæ*, *Thyssa-getæ*) might lead to the supposition that they were connected with the Getæ of Europe.

The Massagetæ are described by Herodotus as a numerous and powerful nomadic people, who resembled the Scythians in their dress

and mode of life. Gold and silver were plentiful among them, obtained no doubt from the Altai range; but no iron or silver was found in their country. They were however in a very low state of civilisation, even for a nomadic people. They had a community of wives; and their aged people were killed and eaten by their relations.

MASSICOT. [LEAD.]

MASTER AND SERVANT. [SERVANT.]

MASTER OF A SHIP. [SHIPS.]

MASTER OF ARTS. [ARTS.]

MASTERS IN LUNACY. [LUNACY.]

MASTIC. A name given by manufacturers to the oleaginous cements which were formerly used to a great extent both at home and abroad, but which lately have been entirely neglected. The normal composition of these materials appears to consist of a mixture of about 7 parts of litharge (the red protoxide of lead), with 93 parts of burnt clay, ground to a very fine powder, and applied by ordinary plasterer's tools, after being mixed with a sufficient quantity of pure linseed oil to reduce the mass to a tenacious plastic state.

The best mastics were formerly considered to be the Hamelin's mastic, in England, and the mastic de Dhil in France; the former material was largely used in King William Street, City, but it was far from successful, and very costly.

MASTICH, commonly but improperly termed gum mastich, is the produce of the *Pistachia lentiscus*, var. *Chia*, a small tree, native of many of the shores of the Mediterranean and islands of the Archipelago. In the island of Scio much attention is paid to the collection of it. About one-third of what is there obtained belongs to the Pasha, and constitutes the fine sort called seraglio mastix, mostly sent to Constantinople. Between the 15th and 20th of July slight incisions are made transversely in the stem and larger branches, whence flows a resinous juice, which gradually thickens, and either adheres or drops on the ground. That which remains attached is removed by an iron instrument, and is collected between the 24th and 31st of August. Two gatherings occur in this space of time. What remains after the tribute to the Pasha is deducted yields two sorts, the so-called seraglio kind, and a second, chiefly sent to Egypt. A third sort is sent to European markets; and of late the finest kind also reaches our marts. This occurs in small isolated pieces, called *tears*, seldom so large as a common pea, from attrition covered with a white dust, nearly transparent. Mastich in sorts has various impurities, and is sometimes mixed with sandarac.

Pure mastich has a mild, agreeable odour, and an aromatic taste; by chewing it softens, and becomes sticky or adhesive. With a gentle heat it melts; ignited, it burns with a strong balsamic odour. It is not at all soluble in water, but is soluble to a great degree in alcohol, and entirely so in ether and fixed oils. Its chemical composition is a very small quantity of volatile oil, and two kinds of resin: one, to the amount of 90 per cent., soluble in alcohol, possessing acid properties, hence called mastich acid; and another, to the amount of 10 per cent., insoluble in alcohol, called mastichine, considered by Bonastre to be a subresin.

Mastich is chewed by females in the East, to sweeten their breath and strengthen their gums; in Europe it is used as a dentifrice, and to stop decayed teeth. It is also an ingredient in pastilles, and perfumes, such as eau de luce. But its chief employment is as a spirit-varnish.

MATCH, in gunnery, is a material employed in firing military mines or in discharging pieces of ordnance. Before the invention of fire-locks, hand-guns or small-arms were fired by matches, which the soldiers carried with them on service; and match-lock fire-arms are still used in some parts of Asia.

What is called *slow-match* is only a piece of slightly twisted hemp which has been well soaked in a strong solution of saltpetre with boiling water. When fire has been communicated to it, it burns very slowly, and a piece one yard long is scarcely consumed in eight hours. In use, the end to which fire has been applied is blown upon by the breath, when it is capable of setting fire to gunpowder or to the cotton-wick inserted in the composition which fills a fuse.

The materials employed in the formation of *quick-match* consist of a mixture of saltpetre and mealed gunpowder with spirit of wine and rain-water. The water in which the saltpetre is put, is made to boil for an hour in a copper-vessel, a wick of cotton being coiled in the liquid; the alcohol is then added, and the mixture is allowed to simmer over a slow fire for a quarter of an hour. Some of the powder is afterwards introduced, and the whole is left during twenty-four hours. The cotton is then wound on a reel and the remainder of the powder is sifted over it. The match is then left for several days in order that it may become thoroughly dry, after which it is fit for use.

MATCHES; CONGREVES; LUCIFERS. The manufacture of these humble and cheap articles marks a curious stage in the progress of civilisation, where luxuries become conveniences, and then necessities. The friction of two pieces of dry wood we now regard as a barbarous mode of procuring light; yet it is a scientific one, where the materials for a quicker process are wanting. The flint and steel had a long reign in this country; the tinder-box formed an item in Wolverhampton manufactures; and the sulphur-tipped matches, arranged in bunches spread out in fan-like manner, formed the stock in trade of many an

itinerant dealer. As mechanical ingenuity supplied the flint and steel and tinder-box to supersede the rubbing sticks, so has chemical ingenuity made a wide step in advance, by showing how to furnish the little splints or matches with a composition which will kindle by slight friction.

Whether called *Congreves*, *Lucifers*, or *Instantaneous Lights*, these small but valuable articles are now made in almost inconceivable quantities. Hand cutting has long been unable to produce the splints in sufficient quantity; nothing less than steam power can do this. At one among many saw-mills in London, these matches are made in the following way. The wood employed is American yellow pine. It is first sawn into blocks about 12 inches long, 5 or 6 wide, and 3 thick. Several of these blocks are placed in a machine where a number of revolving cutters, worked with great rapidity, slice the blocks up into layers, and cut the layers into splints. One machine will cut up two million splints in a day. The splints, as liberated from the machine, slide down into another room, where women and girls tie them up in boxes, the boxes in parcels, and the parcels in bundles. These splints are sold by the *hogshead* to the lucifer match makers, each hogshead containing perhaps two million splints. At one saw-mill alone, it is estimated that the timber of four hundred large pine trees is cut up yearly for lucifer matches; and there are some establishments in England where as many as *five million* splints are made in a day. If the splints are to be cylindrical instead of square, the wood is shaped by being forced through small circular apertures in a metal plate: great pressure, and great sharpness at the edges of the holes, being necessary. But Germany exceeds even England in this branch of industry, as in most other kinds of wood-work. In Saxony, undipped matches, two inches in length, can be bought for 5 thalers per million, about 1400 for a farthing; and boxes to contain them are sold at 2d. per 100. At various places in Bohemia, untipped splints are sold wholesale at a price that scarcely amounts to one farthing per 3000; and at Schüttenhofen tipped matches, boxes and all, containing 80 matches in each box, are sold at the rate of about one penny for a dozen boxes. This degree of cheapness was attained in 1851; and it is likely that prices have lowered rather than risen since.

The chemistry of matches has undergone curious changes. At one time *phosphoric tapers* were made,—complex, dangerous, and expensive. These were supplanted by *phosphorus bottles*, in which sulphur matches were ignited by contact with a bit of phosphorus. A more scientific but less-used arrangement was the *pyrophorus*, in which light was produced by exposing to the air a calcined mixture of flour, sugar, and alum. The *instantaneous light* of Volta was an elaborate apparatus for producing light by the action of electricity upon hydrogen. *Dobereiner's* instantaneous light was a little less complex than this. The *light-syringe* was a kind of squirt, which ignited a piece of German tinder by means of the heat expelled from air when powerfully condensed. All of the above were superseded, for popular use, by the *oxymuriate matches*. Chlorate or oxymuriate of potash was mixed into a paste with gum and vermilion; matches were tipped with this composition; and when the tipped end of a match was dipped into a bottle containing a bit of asbestos moistened with sulphuric acid, it instantly ignited. Elegant metal boxes fitted with this apparatus had a very extensive sale for many years, at prices which gradually fell from a guinea to a shilling. It was not until friction was rendered adequate to the kindling of a match, that the principle of cheapness came fairly into play, by allowing the makers to dispense with liquids, bottles, and complicated arrangements. The *congreve* vanquished all competitors as a light-giver. The chemical composition which gives to the matches their easy-igniting power, can now be bought at a very low price; and as children are chiefly employed in the manufacture, the matches can be sold extremely cheap. Whether the colour be red, yellow, brown, blue, or green, the composition possesses the requisite quality in respect to ignition by friction; and chemists are now acquainted with many such. There are many processes and compositions adopted. In one, the matches are dipped into a mixture of phosphorus, oil of turpentine, and flowers of sulphur; and afterwards into a mixture of gum arabic, chlorate of potash, and soot. In a second method the composition consists of chlorate of potash, phosphorus, gum arabic, and gelatine; the matches being dipped into melted sulphur before being dipped in this composition. In a third method, the composition consists of gum arabic, vermilion, phosphorus, and saltpetre. *Chlorate matches* are dipped into a mixture of chlorate of potash, flowers of sulphur, powdered sugar, gum arabic, and vermilion. The dipping of the end of the splint into melted sulphur, and then into a melted composition of which phosphorus is one of the ingredients, is a very dangerous employment, which has led to many sad calamities. It is also found that the phosphoric fumes tend to induce jaw-diseases, and other maladies, under which the work-people suffer. There is a kind of phosphorus, called amorphous or allotropic, which is said to be free from many of the evils of common phosphorus; but various circumstances have prevented its introduction to any great extent in the match manufacture.

MATERIA MEDICA is that branch of medical science which treats of the articles employed in the practice of medicine, and embraces an explanation of the nature and modes of action of those substances which are had recourse to in order to restore the healthy state of the human frame when its functions or structure are impaired by disease

Thus defined it comprehends both pharmacology and therapeutics. The former means an account of drugs, simple or prepared, in reference to their physical character, natural history, commercial history, chemical composition, and modes of exhibition. The latter means an exposition of the principles which should regulate their employment. The pharmacological part of the subject is sufficiently treated of under each article, as it presents itself in alphabetical order, and it is only requisite to treat here of the general principles involved in their practical application. For the full and satisfactory comprehension of this department, a previous knowledge of the structure of the body, or anatomy, and, above all, of general anatomy, and of the respective duties or offices performed by its component organs while in a state of integrity, or physiology, and of the various degrees of departure from these, when from any cause they become deranged in their action, or pathology, and the signs by which the morbid states are indicated, or nosology, is required. These departments of science are studied only by those persons who intend to follow the medical profession, and at their hands only can a skilful employment of medicines be expected. Something however may be done for the advantage of the public by pointing out how medicines act, and in what way they prove remedial. The object of the administration of a medicine is to arrest the progress of diseased action, and to remove the consequences of its existence, that is, to restore the individual to perfect health, such as he enjoyed before the organ or organs received the impression of the morbid cause; or where both or either of these objects cannot be accomplished, so to retard the career of the unhealthy operations, as to prolong life to the latest possible period. To improve and perfect this most important branch of the healing art is the end and aim of all the other branches of medical science. The means of accomplishing this object have varied in the different stages of human civilisation, and according as different theories of the nature or cause of diseases have prevailed. Many of the medicines formerly in use were of a disgusting or repulsive nature, or of a kind devoid of any active principle, and therefore inert. Many also owed their introduction into practice to superstition, credulity, or a misapplication of the principles of natural and chemical philosophy, and have long been discarded by scientific practitioners, though frequently retained by the populace or by quacks. The medicines used in the present day are still drawn from all the three kingdoms of nature, though the animal kingdom yields few, the vegetable kingdom a considerable number, and the mineral kingdom the greatest number and generally the most active.

In general few articles produce much effect on the human frame, either in a state of health or disease, which are not possessed of marked sensible qualities, impressing the senses of smell or taste in a distinct manner. Hence bland insipid articles are mostly better fitted to furnish nourishment than medicines, being completely digested, and creating no disturbance or change of action of the vital powers of the system; medicinal substances on the contrary do not appear to be thoroughly digested, but a portion remaining unassimilated acts in some measure as a foreign body, and produces a stimulant or alterant effect on the vital power. Many medicines are indeed absolutely poisonous if given in large doses, or where no diseased state of the system requires their administration. For disease often gives to the system a power of sustaining the action of a dose of medicine which would produce serious disorder if given to a person in health; the morbid state of the system seeming to act as an antidote to the medicine, while the medicine acts as an antidote to the disease—health being the result of their neutralising power.

Medicines produce two distinct effects: one termed the primary, or in some cases, as when given to a healthy person, the physiological effect; the other secondary, or curative, which can only take place when there exists a disease to be removed. The former is generally uniform or constant; the latter too often variable and uncertain. To lessen the degree of uncertainty in the latter and most important of the two kinds of action, many zealous medical men have instituted experiments with different medicines on themselves or others; while chemists have carefully investigated the chemical composition of the articles, and sought to discover their active principles, or to explain their modes of action. Notwithstanding these valuable aids, therapeutics is still the most imperfect of all the departments of medical science, partly from the difficulties inherent in the subject, and partly from inability in medical men to weigh correctly the evidence respecting the effects of medicines. The union of several articles in one prescription, by which we attempt by one stroke to remove several symptoms, tends still further to obscure the results, and to vitiate the conclusions which may be drawn. The polypharmacy of the ancients has been in a great measure abandoned, but still it must be confessed that simplicity in prescribing is not sufficiently studied. (Holland's 'Medical Notes and Reflexions on Medical Evidence, and on Methods of Prescription.') On the opposite hand, the attempts to isolate the supposed active principle of many vegetable remedies, and to administer it apart from the others, though in some instances advantageous, by diminishing the size of the dose, or concealing the unpleasantness of the taste, have not produced the consequences expected; for example, in most cases *cinchona bark* administered in some of the old preparations will be found a more valuable tonic than *quinine*. The superiority of many mineral waters, which contain a variety of ingredients in a state of extreme dilution, over the exhibition of the saline materials

in a less quantity of liquid, seems to militate against the practice of excessive concentration.

The introduction of new substances into the *Materia Medica*, by the discovery of new plants, or by the progress of chemistry, may supply deficiencies in the catalogue of remedies. But less benefit to mankind will flow from a multiplication of remedies, than from the establishment of clear and scientific rules for their administration. Every improvement in anatomy and physiology will promote the advancement of therapeutics, by leading to greater precision in the employment of medicines. For nothing is more certain than that medicinal substances act upon special parts of the body, in preference to others, and in many instances on those which are diseased rather than on those which are sound. The careful investigation of the modes of action of medicines is worthy of the best faculties and energies of medical men, and every contribution to this department of science should be regarded as an incalculable benefit conferred on mankind.

(Pereira's *Elements of Materia Medica*; Vogt. *Lehrbuch der Pharmakodynamik*, and Headland *On the Actions of Medicines*.)

MATERIALISM is a name applied to any philosophical system which denies the existence of a spiritual or immaterial principle in man, called the mind or soul, distinct from matter, or which (changing the phrase) denies the immateriality of the soul. The name is applied to systems which differ very widely from one another, in respect of the consequences deduced from the denial of the soul's immateriality; and thus it comes to pass that the popular meaning of the word has become loose and incorrect, comprehending what are no better than accidental consequences of the pure and proper idea. Such accidental consequences are the denial of a future state and absolute atheism; and it need not be said that atheism and materialism are treated in current conversation as convertible expressions.

The name materialism also is one of that sort for which Mr. Bentham has constructed the epithet *dyslogistic*. As applied in current conversation, it always carries with it censure. This arises, of course, from the nature of the accidental consequences which have been indicated, and which mankind regard with horror; but inasmuch as the name still continues to be applied to systems from which unchristian and atheistical consequences are expressly excluded, and even to some systems (such as that of Hartley) which admit the existence of a separate soul, but in whose method of explaining mental phenomena there is a dash of materialism, the censure that has come to be indissolubly associated with the name often falls with grievous injustice. Indeed there is hardly a single word in the whole range of philosophic terminology better fitted to exemplify the evils of looseness of application, or of allowing feelings to tinge and discolour the notions conveyed by names.

The systems to which the name materialism is applied may be roughly distributed under a threefold division. First, it is applied (as has been already said) to a system like that of Hartley, which admits the existence of a soul, but which, attempting to explain mental phenomena physically or by movements arising out of the bodily organisation, seems to imply materialism. Secondly, it is applied to the systems of Hobbes and Priestley, and of the French school of writers, of which De la Mettrie may be taken as a specimen, which distinctly deny the existence of a soul as a separate principle in man, but which do not deny either a God or a future state. In the systems of these writers is evolved the pure and proper idea of materialism, divested of all unnecessary consequences. Thirdly and lastly, the name is applied to systems like that of the ancient Epicureans, which deny both a future state of rewards and punishments and a Divine Creator, systems for which atheism would be the better name, inasmuch as materialism fails to denote their more important and distinctive ingredients.

The following is a brief summary of the views of Dr. Priestley, who has more formally than any other writer enunciated the principles of materialism in the pure and proper sense of the word. He denies the existence of a separate immaterial principle in man, called the mind or soul, because he thinks that an immaterial principle could not exist in union with the material body, and because he thinks, further, that all mental phenomena (as they are called) may be explained by means of supposed movements arising out of the bodily organisation. The method by which he thus explains mental phenomena is that of Hartley. [HARTLEY, in Brog. Div.] Adopting this philosopher's hypothesis of medullary vibrations, he defines mental phenomena as medullary vibrations perceived; and he contends, principally from the analogy of brutes, that bodily organisation is adequate to produce perception. Thus, and by means of such hypothesis, does he dispense with the hypothesis of a separate immaterial soul. But, denying the existence of a soul, separate from the body, and capable of surviving when the body perishes, he does not yet deny the immortality of man, and a future state of rewards and punishments. On the contrary, he distinctly affirms these on the authority of Scripture. It is needless to add that Dr. Priestley does not deny the existence of a God. [PRIESTLEY, in Brog. Div.]

One word more on the absurdity of coupling the denial of a future state with the denial of an immaterial soul, and of making atheism synonymous with materialism. To deny a material soul is necessarily to deny an immortal soul, but not therefore to deny an immortal man. And even to deny the existence of everything save matter in the universe, is not necessarily to deny a Divine principle, as is shown by

many of the ancient schools of philosophy [ELEATIC PHILOSOPHY], nor even to deny a moral governor, as is shown by the philosophy of Hobbes, who, denying in one part of his writings the existence of all spirit, and in this respect carrying his views further than Dr. Priestley, yet makes God the corner-stone of moral and political science. [HOBBS, in Brog. Div.] Hobbes distinctly says that there being nothing, in his opinion, but matter in the universe, it follows that God is matter.

But it is to be remarked, in opposition to materialism, even as it is put forth by Dr. Priestley, that it is devoid of philosophical foundation, and rests on a disregard of the limits of true philosophy. Its truth cannot be tested by observation. It rests altogether on hypothesis and conjecture. When we go beyond what are called the qualities of the mind, or of matter either, and speculate upon what it is itself, whether it is something else, or different from that something, whether it has or has not an existence, we have no help but in supposing and conjecturing and imagining. Such speculations may doubtless be interesting, and they may have their use too as an exercise for the imagination, but we cannot calculate upon their results. Much mischief is done, moreover, by mixing up these results with the results of observation, by jumbling together conjecture and philosophy. The true philosopher, not despising, but setting aside as irrelevant to his object, all speculations on the origin and nature of mind, or of matter either, will start from these as first principles, and will apply himself to observing their qualities and capabilities and laws; and the results will be sound psychology and sound physics.

The converse of the word materialism is immaterialism. This is used only as an abstract term, and even thus very seldom, spiritualism being generally used in its place.

MATERIALS FOR BUILDING. In some of the previous articles reference has been made to the conditions which should regulate the application of particular building materials [ATMOSPHERIC INFLUENCE; FOUNDATIONS; MASONRY]; but the leading principles connected with their selection, and the mode of their applications, are of such paramount importance to all parties connected with this branch of the constructive arts, that it appears desirable to allude, in general terms at least, to their nature. The manner in which this will be done will be by noticing, in the usual order, the materials used in the various details of a building.

External walls (which are mainly required to resist the transmission of moisture from the ground upwards, or from the exterior to the interior of a building, and to maintain an equable temperature in the interior if possible,) may be constructed of either stone, brick, or wood, according to local circumstances; provided the requisite precautions be taken to guard against the destructive action of humidity, or against the various mechanical efforts exerted, and that there be no danger from the propagation of fire, in cases where many buildings are in proximity to one another. The stone may either be used in large or small rough blocks, devoid of bedding or of regular vertical joints; or it may be used in the form of coursed masonry in the manners described under that head; and the only general principles it may be desirable here to allude to with respect to the use of stones of various descriptions, are, that such of them as are dense and of small absorptive powers should be used near the ground; whilst the use of the lighter and the more hygrometric ones must be confined to the positions where they will not be exposed to great efforts of compression, or to external sources of moisture; and care should be taken that the stones are in no case laid with their planes of bedding otherwise than in the direction which they may have occupied in the quarries. The various descriptions of stones (such as the granites, whin stones, slates, marbles, carbonates, argillo-carbonates, and sulphates of lime, and the magnesian limestones) have already been alluded to in the articles quoted, or they will be finally discussed under that of STONE; so that, for the present, it may suffice to say that any material of this description may be advantageously used for building purposes when it is uniform in its grain, or in its molecular structure; when it has comparatively small powers of absorbing water; and when it is not a very ready conductor of heat. The latter condition is too often neglected, and it is on this account that many of the buildings in cold, moist, countries, present hygienic properties of a very dangerous character; for the condensation and the evaporation which are thus continually going on, must render latent a great amount of heat furnished by surrounding objects. The absorptive powers of stones have an important bearing, not only upon the comfort of the interior of the buildings in which they are employed, but also upon their durability, on account of the disintegration and decay which attends the evaporation of the salts they are able to liberate from their original combinations in the stones. It appears, however, that the mere fact of the existence of great powers of absorption does not constitute an absolute reason for the rejection of a building stone; because there are some materials of this class which are of great constructive value, but which are highly absorbent; such as the Yorkshire sandstones, and some of the silicious conglomerates. The structure of a stone has a marked influence upon its powers of resistance to natural external causes of decay, and it is found that the more highly crystalline materials are the most durable; whilst those in which the molecules of the stone are both of an earthy and of a decidedly marked sub-crystalline character (as is often the case with the inferior varieties of the oolites), are sure to decay in an irregular manner. Some descriptions of granite even

are exposed to decay in the open air, on account of the differences in the molecular structure of their constituent elements.

Many of these remarks will apply to the choice of bricks for building purposes; for their relative values will depend upon their powers of resisting the transmission of water, their non-conducting powers, and their durability under the ordinary action of the atmosphere, when exposed for a long time to its effects. In many cases walls have been, and still are, executed of unburnt clay, either rammed into moulds which enclose the space to be occupied by the wall itself (in the manner used in the western counties of England, where it is known by the name of *cobb walling*), or in the form of unburnt bricks (as in the walls of Assyria and of parts of Egypt), and when due precautions are taken to isolate the lower parts of such walls from the ground, and to protect them from heavy rains, they certainly make very warm and comfortable even though temporary structures. The total disappearance of the domestic structures of the nations of antiquity which adopted the use of unburnt clay, whilst the structures erected at the same period of the more durable burnt bricks have survived to our times, prove (if such proof were needed) that the latter alone should be employed in buildings which are likely to be long exposed to distinctly marked atmospheric influences. In fact, no mere mechanical preparation of the silicates of alumina (the base of all clays) can give those materials the property of a permanent cohesion; and no stable combination between the various elements can be effected, without the intervention of fire; or, in other words, the pyrogenous combination of silica and alumina are the only stable ones. A small proportion of the carbonate of lime in clays is a desirable condition; for it facilitates the fusion of the other ingredients; but a large proportion of carbonate of lime entails inconveniences which have already been alluded to. [BRICK.] It may be suspected that much of the value of brickwork depends upon the reaction of the bricks themselves upon the mortars, or upon the cementing materials employed; and it would therefore seem that, for the purposes of hydraulic engineering, or of building in water, it is desirable to use bricks which, even after calcination, retain a certain proportion of soluble silica, in a state to allow of its being taken up by the lime around it. The remarkable preservation of the underburnt Roman bricks, or of the soft kiln-burnt bricks of the middle ages, when used in positions where running waters could not affect them, may be explained by the fact of the existence of some statical chemical balance of this description. For general purposes however, it may be sufficient here to state that the hardest, and most thoroughly burnt, bricks only ought to be used in the exposed faces of walls; that only the best hydraulic limes [LIME; MORTAR] should be used in conjunction with them; and that, without entering into any abstract calculations of stability, no external walls of houses in exposed positions, should ever be constructed of less thickness than of one and a half brick; so as in fact to intercept the passage of water from the exterior to the interior by a vertical joint of mortar. The combination of brickwork and of timber sometimes admits of the attainment of the latter condition, when the total thickness does not exceed that of one brick; but in this case the bond of the work cannot be theoretically satisfactory.

In many of our colonies, and in many well wooded countries of a more ancient date, the use of timber for external walls takes place to a great extent; nor, provided that the passage of moisture from the ground, by capillary action, be intercepted, that the rain be prevented from lodging on the upper surfaces, and that there be no danger from the communication of fire, can there be any rational objection to this mode of construction. Where wood is very abundant, as in the United States, Norway, &c., it is used simply in logs; and those logs are laid upon one another without being squared, but are only halved together at the angles; the interstices are then filled in with clay, or with lime and hair; and the exterior and interior surfaces of the walls thus formed, are then carefully plastered. In countries where wood is more valuable, the style of construction becomes more elaborate, and the framing is executed with squared timber, either filled in with brickwork-panels, called technically "brick-nogging," or with quarterings, which are subsequently either covered by "shingles," (or small thin pieces of wood laid like slates,) or are boarded, or lathed and plastered. The half timbered houses in our own country, and in Normandy, may be referred to as illustrations of all these last named varieties of wooden construction; and of the remarkably picturesque effects they were able to produce. The Swiss *chalets* of the present day are equally worthy of admiration; and it may be worth while to add that when the exposed timbers of such half timbered houses are covered by slates, as is very frequently the case in our own southern provinces, they are but little exposed to the danger of decay, or of fire; but no such palliations of the defects inherent to wood structures can ever guarantee them against the attacks of insects or of vermin.

The principal use of wood is, however, for internal works and fittings; and the selection of the particular description to be used in any position must be regulated by so many local considerations that it is preferable to treat of them in two separate articles. [WOODS, BUILDING; and WOODS, FURNITURE.] The general conditions for their selection and use are, that the woods should be as light and as easily worked as possible, consistently with the requisite degree of strength; that when intended to be used as girders, or for framed carpentry, they should be of a straight, tough, fibrous nature; that the trees

should be felled in the winter, and that, under all circumstances, the wood should not be fixed in a building until the sap, or other moisture it might contain, had been allowed to escape; that a free circulation of air should be maintained around the woodwork of every description; and that especially all contact with a damp, confined, atmosphere should be avoided. As might naturally be expected, woods transmit moisture more easily in the directions of their vesicles, than transversally to the latter; and attention must be paid to this law whenever it may be necessary to employ this material partially in and out of the ground. The attacks of insects, and of the marine boring worms, together with the conditions of decay under the action of wet or of dry rot, must not be overlooked in the inquiry into the value of woods; they are discussed under PRESERVATION OF STONE AND WOOD. A very essential property in woods used for decorative works is that they should not be exposed in any serious manner to absorb atmospheric, or in fact any external, moisture; and that they should not warp under changes of temperature. To a certain extent, all woods are exposed to this inconvenience; but the superior descriptions of mahogany, oak, and fir, do not warp in any serious or dangerous manner under ordinary changes, provided that due care has been observed in their seasoning before placing them in the work. Some woods again have a distinct action upon metals, such as the oak produces upon iron, or even occasionally upon lead; but the circumstances under which this action takes place are not sufficiently known to warrant any decided general observations with respect to it. Contact with other building materials does not seem to affect the durability of wood, provided the circulation of air around the latter be not prevented.

It is rather a curious illustration of the practical working of injudicious fiscal laws, that the use of timber in external house construction should have prevailed in such places as Caen, where stone is to be procured at the very gates of the town; simply because in the middle ages there was a heavy octroi, or toll, on building stone. Many local peculiarities in the use of building materials may, no doubt, be explained in the same manner; as, for instance, the peculiar size of English bricks, or the Mansard roofs of France.

The materials used for covering the rough surfaces of walls, or for producing a smooth surface upon framed timber partitions, are either obtained from the calcination of the carbonates of lime, of the various classes of cements, or of the sulphates of lime; and the same class of materials is, as is well known, largely applied for the purpose of connecting the small materials used for walling. The respective qualities of the LIMES, MORTARS, CEMENTS, and PLASTERS will be found under those heads, so that it may suffice here to say that, in consequence of the greater rapidity with which the real plaster (the dehydrised sulphate of lime) sets, it is always employed internally to render or cover the walls or partitions, when that can be done economically. It is required, in such cases, to produce an even surface to receive the wall decorations, which surface should at the same time be so far absorbent and non-conducting as not to allow the moisture in suspension in the rooms to condense upon, or to remain upon, the sides of the rooms; and for this purpose the real plasters possess properties which no other materials can boast of. In the greater part of Europe, however, plaster is both rare and costly, and its place is supplied, more or less satisfactorily, by the lime and hair, and the fine stuff, as our plasterers designate the various descriptions of coats they obtain from the purer carbonates of lime treated in peculiar manners, according to the particular parts of the operation. The hydraulic cements are sometimes used for internal plastering or wall decorations, when moisture is to be contended with; and the oddly named artificial cements obtained by the second calcination of the sulphates of lime, such as the Keene's, Parian, or Martin's cements, are used for skirtings or for wall decorations, when particularly hard close surfaces are required, and it may be necessary to paint them immediately. The plasters do not resist the action of the external atmosphere, or its changes of hygrometric state, although when proper precautions are taken the plaster of Paris stands tolerably well on external walls near that town; but, as a general rule, none but the hydraulic cements should be used for this particular description of work, and even with them it is essential to prevent moisture from lodging upon their surfaces, especially in climates exposed to sudden frosts and to heavy winter rains. Nearly all this class of materials requires to be protected by a coating of oil-paint, or of some other preparation able to oppose the absorption of water.

Roofs are covered in various ways, depending mainly upon the economical conditions of the locality,—namely, either by thatching with straw or reeds, by shingles, by tiles, by slates, or by one or other of the metals, iron, zinc, copper, lead, or tin; and, in very temporary buildings, even by tarred felt. Thatching makes a warm and an exceedingly picturesque covering; but it is objectionable on account of its retaining moisture under some circumstances, of its weight, and of its inflammable nature. In America and in Norway small wooden slabs, cut like slates, are used, under the name of *shingles*, and if properly nailed and weighted down in positions exposed to violent winds they answer tolerably well, though, of course, they are exposed to the same objection as the one above alluded to—namely, their inflammability. Shingle roofs were formerly common in England, and specimens yet remain on some church spires. In all densely peopled districts, therefore, slates or tiles are used for the commoner descriptions of houses, and the metals are used for more important buildings

under the conditions discussed under *Roof*. The precautions to be observed in all these cases are—1, that an efficient circulation of air should be kept up within the roof; 2, that when metals are used, the contraction and expansion should not be interfered with; and 3, that when two metals are employed, they should be placed in such manner as not to allow a destructive galvanic action to take place.

Metals are also used in building operations in other modes than simply as coverings, and iron in its various forms has of late become an article of the greatest importance to the constructive or to the decorative builder. Cast-iron is largely used for girders, columns, railings, pipes, sashes, &c.; wrought-iron is becoming daily of more and more importance for girders, for roof framing, for pillars, railings, tanks, doors, and countless purposes of common life. Lead, copper, zinc, tin, and their alloys are used for many details of building, and for the distribution of those essential elements of modern comfort, gas and water: precautions, however, are requisite in their application to secure them from certain chemical actions which may be produced by the extraneous matters contained in the fluids so distributed. [WATER SUPPLY.] It would appear that if the new metal aluminium were obtainable at a cheap rate, it would constitute one of the most valuable additions to the list of building materials, on account of its lightness, its tenacity, and its powers of resisting the action of the atmosphere.

Glass in its various forms is a material so generally known that it will be sufficient merely to mention it; and the use of oil-paints for purposes of decoration or of preservation will be discussed under *PAINT*. The use of the solutions of silica, and of the other various substances applied of late years for the protection of woods from wet and dry rot, will be noticed under the article *PRESERVATION OF STONE AND WOOD*, already referred to. Wall linings, or *PAPER HANGINGS*, will be noticed under the latter head.

MATERIALS, STRENGTH OF. The strength of any material object, as a rod, bar, beam, chain, or rope, is that power by which the substance resists an effort to destroy the cohesion of its parts. It evidently depends on the disposition of the particles relatively to each other, on the intensity of the force by which the particles cohere together, and on the manner in which the straining power is applied. The inquiry into the laws by which the materials employed in the construction of edifices or machines resist the strains to which they are subject is of considerable importance, because upon a just adaptation of the strength at any one point to the strain there experienced (and an excess or deficiency of the former is sometimes equally injurious) depends the stability of the whole structure.

Whatever be the constitution of a rod or of a beam, the relation between its strength and the strain to which it may be exposed can be made the subject of mathematical investigation only by imagining the material to consist of an infinite number of particles arranged in lines (like fibres or threads) parallel to each other in the direction of its length. The particles in each line must be supposed to cohere together by powers exerted in that direction, and the several lines to cohere laterally with forces which may or may not be equal to those exerted longitudinally. In homogeneous bodies, as glass and some of the metals, the particles may be supposed to be symmetrically disposed throughout the masses, and to attract each other in every direction with equal powers: but the case is different in other bodies, particularly in timber; for in such bodies the lateral cohesion of the fibres is much less powerful than the longitudinal cohesion of the particles in each fibre. In ropes the fibres have no lateral cohesion, and the strength depends on the twisting of the fibres together; in consequence of this, as the latter can scarcely be separated from each other in the direction of the length of the rope, the cohesion of nearly all the particles in any transverse section must be destroyed before a disruption can take place.

A rod of any material, consisting of parallel fibres as above supposed, being placed in a vertical position, and strained by a weight applied at the lower extremity, the particles in every fibre will be separated from each other by the action of the weight, and consequently its length will be increased. The cohesive power by which the particles are kept together will, in most cases, be diminished by the separation; and if the weight be sufficiently great, or if it be allowed to act during a sufficient length of time, the cohesive power will be eventually overcome; that is, the rod will in some parts of its length be torn asunder. But before this occurs, since all bodies possess a certain degree of elasticity, on removing the weight the attraction of cohesion will cause the separated particles to return towards their original positions; or the rod will become nearly of the same length as at first. That it does not exactly become so, in general, arises from the imperfect elasticity of the material, on which account the particles come to a state of rest at augmented distances from each other. The elongation of the rod when strained by a weight, and the amount of the weight necessary to produce fracture, will depend on the nature of the material; and, from a want of uniformity in the constitution of materials even of the same kind, though the rods be of like dimensions, great irregularities are found to exist in their power of resisting direct strains. Numerous experiments performed on each of the different kinds of material can alone afford a mean value on which reliance may be placed when it is required to determine the capability of a bar or beam to resist the strain arising from the action of any given force.

If the materials were perfectly elastic, so that the length of the rod

became the same after the removal of the suspended weight as before that weight was applied, the force of cohesion would evidently be proportional to the intensity of the straining power; and this is generally adopted as an hypothesis in investigations concerning the equilibrium between strengths and strains; it being understood that the latter have only that moderate degree of intensity, compared with the former, which is consistent with the permanent stability of the edifice or of the machine. The law just mentioned appears to have been discovered by Dr. Hooke; and as the separation of the particles in any fibre is proportional to the straining power, it follows that, within certain limits, the cohesive power between two particles of an elastic body is proportional to the distances to which one of them is removed by the straining force from the place where it was before at rest. The same law is considered to hold good when the particles of an elastic body are made to approach each other by the action of a compressing force like that of a weight on the top of a vertical pillar.

The power by which the particles in any body resist the action of a force tending to separate those particles in the direction of the length of the body may be considered as constituting the direct or absolute strength; and it is evident that, if the body were of a homogeneous texture, that strength would be proportional to the number of particles in a transverse section; that is, to the area of such section, while the strain is proportional to the weight applied. Therefore, if F designate the cohesive power in a unit of such area, as a square inch, a square foot, &c.; also, if A represent the area and w the weight applied, including that of the body itself, we should have $F A = w$ when the strength and strain are in equilibrio. This formula for the absolute strength may be considered as nearly correct with respect to most of the bodies in nature; and hence (F being determined by experiment) the strength by which a rod of any material resists this kind of strain may be found when the dimensions of the rod are given.

For complete details concerning the experimental values of F , the reader must be referred to the extensive tables which have been published by Barlow ('*Essay on the Strength of Timber*'), Rennie ('*Phil. Trans.*' 1818), Tredgold ('*Principles of Carpentry*'), Hodgkinson ('*Experimental Researches into the Strength of Cast Iron*, &c.), and Morin ('*Leçons de Mécanique Pratique*, vol. iv.), our limits permitting us to introduce only the few determinations which follow.

The area of a transverse section of each rod is one square inch, and the values of F are expressed by the breaking weights in pounds avoirdupois.

English oak	$F = 8,000$ to $12,000$
Fir	11,000 to 13,488
Beech	11,500
Mahogany	8,000
Teak	15,000
Cast-steel	134,256
Iron-wire	93,964
Swedish bar-iron	72,064
Best English malleable iron	60,000
Cast-iron	18,656 to 19,488
Wrought-copper	33,792
Platinum wire	52,987
Silver do.	38,257
Gold do.	30,888
Zinc do.	22,551
Tin do.	7,129
Lead do.	3,146
Rope (1 inch circumference) bore	1,000 lbs., $F = 12,566$
Whale-lines spun by hand (2 in. circumference)	2,240 " 7,037
Do. by machinery ($1\frac{1}{2}$ in. circumf.)	3,520 " 12,582
Rope (3 in. circumf.)	5,628 " 7,858
Do. (4 in. circumf.)	9,988 " 7,845
Cable ($14\frac{1}{2}$ in. circumf.)	89,600 " 5,355
Do. (23 in. circumf.)	255,360 " 6,066

Notwithstanding the irregularities in the column containing the values of F for ropes, it may be concluded that large ropes of a given diameter have less strength on each square inch of their transverse section than those of less diameter; and this is owing, no doubt, to their threads being less twisted together. It may be observed, also, that those woods whose fibres are nearly straight bear much greater weights suspended from them than those whose fibres have considerable curvature.

According to the experiments of Mr. Barlow, it appears that a bar of malleable iron is extended one ten-thousandth part of its length by a direct strain equal to one ton for each square inch in the area of the transverse section: when stretched with ten tons per inch its elasticity was injured, or the bar did not return to its original state.

If the fibres in any material body were exactly rectilinear, so that, a rod being placed on one end in a vertical position, no one of the particles were opposite to the intervals between any two in a transverse section below it, it might be conceived that no force compressing the rod in the direction of its length would produce any other effect than that of diminishing its length. But as we find that all bodies when so compressed may be bent, and finally broken, such a disposition of the particles is destitute of probability. In fact, when a pillar is compressed by a great weight above it, either the fibres, already curved, have their curvature increased, so that the whole pillar bends; or the

particles in some of the transverse sections are forced outwards by lateral pressures arising from the particles above and below their intervals being thrust between them, and then the pillar swells on its whole periphery. The consequence in either case is, that the cohesion of the longitudinal fibres is impaired or destroyed, and the pillar is at length broken or crushed.

The strength of a pillar when so compressed must evidently depend upon the number of particles in a transverse section—that is, upon the area of such section; but since, besides the displacement of those particles from the longitudinal pressure, their lateral cohesion must be overcome before they can be thrust outwards, it is evident that the strength is not proportional to the area, simply, but to some function of that area. No law on which any dependence can be placed has yet been discovered for the strength of a pillar in such circumstances. Euler, from analytical considerations, concluded that it varies as the square of the area; but late engineers have supposed that the square root of the third power of the area more correctly represents the law of the strength.

If a bar or pillar, resting on one end in a vertical position, and considered as a perfectly elastic body, be compressed by a weight acting vertically above it, the purely mathematical theory gives the following equation for the value of the compressing weight when the pillar begins to bend:—

$w = \frac{\pi^2 ad^3}{12l^2} \delta$ (Poisson, 'Mécanique,' tom. i., No. 313); where w = the compressing weight; l = the length of the pillar; a = the area of the transverse section; d = the thickness perpendicularly to the bending surface; δ = the element of deflection; and $\pi = 3.1416$. It follows that, when in two bars of like material a and d are respectively equal, the weights which those bars will sustain without bending are inversely proportional to the squares of the lengths.

It is also found, if w be a weight applied as above, and producing a flexure p , measured at the middle of the bar perpendicularly to its length, that $\delta = \frac{4wl^3}{ad^3p}$: this being substituted in the expression for w ,

the latter becomes $w = \frac{\pi wl}{3p}$. (*Ibid.*, No 314.)

From Mr. Hodgkinson's experiments on the resistance of columns it appears that the shape of their bearing-ends has an important influence upon their power of supporting an insistent weight; for columns with flat and firmly bedded ends carried about three times the weight which broke other columns with rounded ends. It is customary at the present day to consider that the resistance of wrought iron to an effort of compression may be considered to be, at the minimum, 56,760 lbs. on the square inch (it is called by some engineers 67,200 lbs.); and according to Mr. Hodgkinson, if the resistance of cast iron be taken as unity, that of cast steel will be 2.518; that of wrought iron 1.745; whilst that of the best Dantzic oak will be 0.1088; and that of red deal 0.0785. In the cases of cast iron or of other columns the resistance is, however, affected by the ratios of the diameters to the length; and if the value of the resistance be taken at 56,760, and the safety load be taken at $\frac{1}{3}$ of the crushing weight, the following table, translated from Claudel's 'Formules à l'usage des Ingénieurs,' may be considered to represent the loads it is advisable to bring upon solid wrought iron columns.

Ratio $r = \frac{l}{d}$	> 5	10	20	30	40	50	60	70	80
Load in lbs. per in.	11,352	7095	6484	5676	4824	4044	3391	2838	2384

This table is taken in preference to the one given in the same work for the strength of cast iron pillars; because the latter table is based upon a coefficient of resistance which seems to be rather too high, and it would therefore be preferable to affect the results of the table given by the ratios of the various materials above quoted. The various essays by Messrs. Chevaudier and Wertheim, 'Sur les Propriétés Mécaniques des bois' should be consulted by all engineers and architects who may be called upon to use those materials under heavy loads. It must also be observed that the shape of the column or body operated upon will materially affect its resistance to compression, for according to Navier and Duleau, with the majority of woods the resistance is in the ratio of $\frac{ab^3}{b^2}$, when the section is triangular; it is $\frac{b^4}{b^2}$ when the section is square, and $\frac{d^4}{b^2}$ when the section is circular.

The most important inquiry concerning the strength of materials is that which relates to a beam or bar supported at its extremities on two props, and strained transversely by a weight acting perpendicularly to its length at a given point between the props.

In order to simplify the investigation, it is usual to imagine that the beam, its breadth and depth being supposed uniform, is made to rest on one prop at the place where the weight may have been applied in the former case, suppose in the middle of its length, and that from the points where the two props were situated weights are suspended equal to the reactions of those props in consequence of the first weight;

that is, to half the whole weight in the middle. Then, supposing the deflection of the beam to be very small, so that, in the former case, the beam did not slide on its point of support, the effect of the two weights to break the beam on its single prop will be the same as that of the one weight applied as at first supposed. Again, if a beam of equal dimensions with respect to breadth and depth were fixed at one end horizontally in a wall, the part projecting from the face of the wall being equal in length to half that of the former beam; and if a weight were applied at the opposite end equal to each of the two weights applied to the beam on one prop, the effect of this weight to break the beam at the face of the wall will be equal to that of the two weights to break the beam on the one prop, or of the double weight to break the same beam on two props. The investigation for the case at first supposed is therefore reduced to that of finding the strength of a beam attached at one end to a wall, and strained by a weight at the opposite extremity.

Let AB (fig. 1) be the face of a wall, and let MN represent a vertical section of the beam in the direction of its length. Let it be supposed that the beam consists of an infinite number of fibres parallel to MP ; then, if these fibres were supposed to be rigid and incompressible, the effect of a weight at P would be to bring the beam to an inclined position, as $m-n$, producing a fracture on the line MQ by drawing the particles on that line away from those which were at first nearly in contact with them. But from experiment it is found that, when a beam is so strained, while the upper fibres are in a state of tension, the lower ones are in a state of compression; and consequently that there is a certain point O in the depth of the beam at which neither of these effects takes place. A line passing through this point perpendicularly to the plane MN is therefore called the neutral axis of the beam, and the termination of the fracture may be supposed to be at O instead of Q ; the fibres below the former point having no effect in resisting the tendency of those above to be broken, yet constituting part of the strength of the beam by the power with which they resist compression, and thus oppose the tendency of the beam to turn about the neutral axis. The position of this neutral axis is uncertain; but Mr. Barlow, from experiment, has found that in rectangular beams of wood (the faces being in vertical and horizontal positions) its distance from the upper surface at M bears to the whole depth MQ the ratio of 1 to $1 + \sqrt{3}$, or nearly that of 4 to 11. Therefore, d representing the depth MQ , let OM be represented by $\frac{4}{11}d$.

Now adopting the hypothesis of Leibnitz, which is founded on the elasticity of the fibres, that the force of cohesion in any one fibre is proportional to the tension to which it is subject, or to the distance of that fibre from the axis about which the beam turns in consequence of the strain; that is, from the neutral axis just mentioned: if x be the distance of any fibre above O from the latter place, and f represent the force of cohesion in the fibre at MP , we shall have $\frac{4}{11}d : f :: x : f \frac{11}{4d}x$: and the last term will express the force of cohesion between two particles at a distance above O equal to x . Consequently, dx expressing the indefinitely small depth of a fibre, we have $f \frac{11}{4d}x dx$ for the cohesive power of a fibre at the same place. But this power acting at a distance from O equal to x , we have $f \frac{11}{4d}x^2 dx$ for the momentum of that force; and its integral will express the strength of all the fibres in the vertical section represented by MN . The transverse section of the beam being supposed to be rectangular, the breadth will be constant; let it be represented by b : then the integral of $f \frac{11b}{4d}x^2 dx$ (between $x=0$, $x = \frac{4}{11}d$), that is $\frac{16b}{363d} f d^3$, or nearly $\frac{1}{23} b d^3 f$, will express the strength by which all the fibres above the axis of O resist the strain.

A corresponding expression for the strength arising from the resistance of the fibres below the neutral axis to the force of compression would be the integral of $f' \frac{11b}{7d}x^2 dx$ (between $x=0$, $x = \frac{7}{11}d$), that is, nearly $\frac{2}{15} b d^3 f'$ (f' being the force by which a fibre at QN would resist compression), and the sum of the two integrals will be the whole strength of the beam to resist a transverse strain. Now the

ratio of f to f' is different in different materials; and if we take $f' = \frac{1}{2}f$ (which is the case in some kinds of wood), the said sum will be $= \frac{1}{9} f b d^2$ nearly.

But when the beam is strained by a weight w applied at p , so that it takes the inclined position $m n$, if we join o and p , and let fall the perpendicular $p r$ on ΔB , we shall have $w \cdot p r$, or (if l be the length of the beam) $w \cdot l \cos o p r$, for the momentum of the weight. Then $w \cdot l \cos o p r = \frac{1}{9} f b d^2$ becomes the equation of equilibrium, w representing the weight which will just break the beam; and when $\angle o p r$, or the deflection, is small, its cosine may be considered as equal to unity. It follows that the strength by which beams of the like material resist this kind of strain will vary as $\frac{b d^2}{l}$.

If a perfectly elastic beam or bar were attached horizontally at one end to a wall, and were strained by a weight w at the other end, the mathematical theory would give for the deflection of the opposite end of the beam (that is, the distance to which this end would be drawn in a vertical direction from the original position of the beam) $\Delta = \frac{w \cdot l}{a d^2 \delta}$ (Poisson, 'Mécanique,' tom. i., No. 310), where Δ = that deflection; l = the length of the beam; a = the area of the transverse section; d = the depth; and δ = the element of deflection. Therefore, if Δ be found from experiment on a beam or bar in which w , l , a , d , are given, we may from this equation obtain δ ; and subsequently the value of Δ may be found for any beam, the materials being of the same kind. Again, the straining power by which a beam fixed at one end to a wall is dilated in the direction of its length is expressed by $a \delta D$ (Ib., No. 308), where D is the element of dilatation. Now, if w be the weight which would produce the deflection δ and dilatation D , we should have $w = a \delta D$; whence $\frac{D}{w} = \frac{1}{a \delta}$; and the first member of this equation being substituted for its equivalent in the above expression for Δ , the latter becomes $\Delta = \frac{D \cdot w \cdot l^3}{w d^2}$; or since the elongation of the whole beam is proportional to the length, and may be represented by $D \cdot l$, if we put E for this elongation when $w = W$, we shall have $\Delta = E \frac{l^2}{d^2}$. Whence the elongation of an elastic rod by a weight or power acting in the direction of its length is to the deflection of the same rod by a weight or power acting perpendicularly to its length, as the square of the depth or thickness is to the square of the length.

The relations between the strength and strain when a beam or bar, as $M N$ in the preceding figure, is fixed at one end in a wall, and when a beam $P' M P$ in the annexed diagram (fig. 2), of equal dimensions with

Fig. 2.

respect to breadth and depth, but twice as long, is supported on a prop at its middle point (the weight at each extremity of the latter being equal to that at the extremity of the former), are the same. Also the angle $v o p$ of deflection ($o v$ being in the direction of $P' o$ produced), when a beam is supported on a prop at q , is equal to $\angle o p r$, or $\angle h o p$, in the preceding figure ($o h$ being drawn perpendicular to the wall, or parallel to the horizon, and the beam $M N$ being equal in every respect to one of the half-beams on the prop). For the angles $m o m$ are equal in both cases; since the weight at p' produces only the same effect as the reaction of the wall: and hence it follows that the angle $h o p$ of deflection, with respect to the horizontal line $h' h$, will be equal to only half the angle $h o p$. The same relation subsists between the deflections when the beam $P' M P$ is supported on the props at the extremities.

It will follow, from what was at first stated, that a beam attached at one end to a wall in a horizontal position will bear suspended from the other extremity only half the weight which the same beam will bear on its middle point when made to rest loosely on the two props. If the ends of the beam were prevented from rising on the props, the strength would, on account of the additional weight necessary to produce deflection or fracture at each end, be increased in the ratio of 3 to 2 nearly.

The following table contains a few of the results obtained from experiments made by Messrs. Banks, Barlow, and Tredgold, on wood and iron, when supported loosely on props and subject to a transverse strain at the middle point. The first column contains the length of the beam or bar in feet; the second, the areas of the transverse sections in square inches; the third, the breaking weights in pounds; and the last, the deflections at the middle points in inches.

	Length.	Area.	Weight.	Deflection.
Young oak (English)	2	1	482	1.87
Ship timber	2½	1	264	1.5
Oak (English)	7	4	637	8.1
New England fir	7	4	420	4.66
Riga fir	2½	1	212	1.3
Teak	7	4	820	4.
Cast-iron bars	3	1	756	
Ditto	3	1	869	

Since the strengths of beams attached at one end or supported on props, the other dimensions being the same, vary as the squares of the vertical depths, it follows that the most advantageous position, when the areas of the transverse sections are equal, is that in which the broadest surface is in a vertical position. In this manner girders and joists in edifices are invariably placed.

When a beam or bar is attached at one end to a wall, or when it turns upon its middle point like the great lever of a steam-engine, if it be required that the beam should be equally strong in its whole length, it should be made to taper towards its extremities. When the depth of the beam is constant, the breadth at any point should be proportional to its distance from the extremity. When the breadth is to be constant, the vertical face of the beam should have the form of the common parabola; and when both breadth and depth vary, a longitudinal section of the beam should have the figure of that which is called a cubical parabola.

If a weight be applied at any point in the length of a beam which is supported on two props, the strain produced by it will be the greatest when it is placed in the middle; and the strain varies as the product of the distance of the weight from the points of support. For let $A B$ (fig. 3) represent a beam supported at A and B , and let c be any

Fig. 3.

point in it. Imagine a weight w to be applied at any point P ; then, by the nature of the lever, $A B : P B :: w$: the pressure exerted by w on the point A , namely $\frac{w \cdot P B}{A B}$; and this term expresses the re-action of

the prop at A in consequence of the weight at P . Then also $\frac{w \cdot P B}{A B}$ is equal to the strain at c produced by this re-action. Again, imagine a weight w' to be applied at P' ; then we shall have, as before, $A B : P' A :: w'$: $\frac{w' \cdot P' A}{A B}$, and this last term expresses the reaction of the

prop at B in consequence of the weight at P' : also $\frac{w' \cdot P' A}{A B}$ is equal to the strain at c produced by this reaction. The sum of these strains is equal to the whole strain at c produced by the two weights. But when P and P' coincide with C , we have $P' A = A C$, $P B = B C$; and the sum of the two strains is $\frac{w \cdot B C \cdot A C}{A B} + \frac{w' \cdot A C \cdot B C}{A B}$; or, putting w'' for $w + w'$, we have the strain at c , in consequence of the weight w'' placed there, equal to $w'' \cdot \frac{A C \cdot B C}{A B}$; and if w'' be a constant weight applied

at any point in $A B$, the strain will vary as $A C \cdot B C$. This rectangle, and consequently the strain, is a maximum when c is in the middle of the line.

If a weight be diffused over a beam which is fixed at one end to a wall, it may be considered as acting at its centre of gravity, which, if the diffusion be uniform, will be in the middle of the length of the beam. The momentum of the strain will consequently be equal to half of that which would result from an equal weight attached to the opposite end.

When a body is compressed in a direction perpendicular to the length of the fibres, the points of support being very near and on opposite sides of the place at which the force is applied, the strain to which the body is then subject has been called by Dr. Young the force of detrusion. This species of strain sometimes occurs in the construction of machinery; but few experiments have yet been made to determine the strength by which materials resist it. From these however it appears that the strength is proportional to the area of the transverse section, and that it varies from four-thirds to twice the strength by which the same material would resist a strain in the direction of its length.

Such machines as capstans and windlasses, and axles which revolve with their wheels, are, when in action, subject to be twisted, so that their fibres tend to become curved in oblique directions; and the strain thus produced is called that of torsion. The most natural way of investigating the strength of materials to resist this kind of strain is probably that which was adopted by Dr. Robison: this mechanician imagined the cylindrical body to be composed of an infinite number of concentric hollow cylinders inserted in each other; and, supposing the whole to be cut by a plane perpendicular to the axis, he conceived that two particles in the circumference of any one of the concentric circles would resist the effort to separate them, by a force proportional to

their distance from the common axis. Hence, if the radius of the whole cylinder be r , and that of any one of the internal cylinders be x ; also, if F' represent the force of cohesion between any two particles in the outer circumference, we have $r : F' :: x : \frac{F'}{r} x$. The last term expresses the like force in the circumference of the cylinder, whose radius is x , and the momentum of cohesion is $\frac{F'}{r} x^2$. But as all the particles in that circumference exert the same power, and the number of particles is proportional to x , it follows that $\frac{F'}{r} x^3$ will represent the sum of all the forces in the latter circumference, and $\frac{F'}{r} x^3 dx$ will represent the sum in a hollow cylinder whose thickness, in the direction of the radius, is infinitely small and equal to dx . Then, by the rules of integration, we have for the strength of the whole cylinder the expression $\frac{F'}{4r} x^4$, which, between $x = 0$ and $x = r$, becomes $\frac{F'}{4} r^3$; and hence the whole strength of any cylinder varies as the cube of the radius.

But the area of any section of a cylinder whose radius is r being $= r^2 \pi$ (π being the half circumference of a circle when the radius = 1) it is evident that $F' r^2 \pi$ will represent the lateral cohesion by which all the particles resist being separated by the force of detrusion. Therefore the ratio between the force of detrusion and that of torsion will be as $r^2 \pi$ to $\frac{F'}{4}$; or as 4π to r .

And since the strength under the latter strain depends on the radius, it is evident that a hollow cylinder must be stronger than a solid one; the areas of the material in the transverse sections being equal to each other.

The preceding reasoning is entirely founded on the supposition that the sections of the various solids considered had but a small importance upon their resistance to the various forces considered; but this is far from being the case in practice, and especially in the case of cast and wrought iron, the resistances of the upper and of the lower fibres of a rectangular beam differ to such an extent as to have rendered it necessary to carry out a long series of investigations into the real forms of solids of those particular materials presenting the greatest resistance. Mr. Hodgkinson, after Tredgold and Barlow in our own country, and Messrs. Morin and Love, after Navier, Coriolis, and Vicat, in France, have studied this complicated question; and the results of their inquiries, so far as the practical arts of construction are concerned, have been already alluded to under GIRDER, in which article also will be found enumerated the principal authors upon the subject it may be desirable for the student to consult. Very useful tables of the resistances of materials to efforts of compression, and of extension, may be found in Carr's 'Synopsis of Practical Philosophy,' 1843; Beardmore's 'Hydraulic, &c. Tables,' 1852; Moseley's 'Engineering and Architecture,' 1843; Willis's edition of Barlow, on 'Materials and Construction,' 1851; and Claudel's 'Formules à l'usage des Ingénieurs,' 1854.

MATHEMATICS ($\mu\alpha\theta\eta\sigma\iota\varsigma$, or $\mu\alpha\theta\eta\mu\alpha$), a name given in the first instance to a branch of knowledge, not as descriptive of its subject-matter, but of the methods and consequences of learning it. The word $\mu\alpha\theta\eta\sigma\iota\varsigma$, and the Latin *disciplina* by which it has been rendered, have been the origin of the vernacular terms *mathematics* and *discipline*, the meanings of which have long since separated. The properties of space and number, the subject-matters of the $\mu\alpha\theta\eta\sigma\iota\varsigma$, have usurped the name; so that anything which relates to them, however learnt, is called mathematics: the Latin word, on the contrary, still retains the signification of a corrective process; and, in speaking of any branch of knowledge, is applied when power of mind is derived from the methods of learning it, as well as knowledge from the results.

The original use of the word mathematics cannot be gathered, so far as we can find, from any express contemporary authority; a few passages in which the term is used without explanation, as one of notoriety, being all that can be cited, and mostly from Plato. Later writers, as for instance Anatolius (cited by Heilbronner), A.D. 270, give the derivation above alluded to. But before the time of Anatolius the meaning of the word had been extended: thus the book of Sextus Empiricus "against the mathematicians" is, as Vossius remarks, directed as much against grammarians and musicians as against arithmeticians and geometers. And John Tzetzes, in the 12th century, includes under the $\mu\alpha\theta\eta\mu\alpha\tau\alpha$ nearly what the universities afterwards called by the name of arts; calling grammar, rhetoric, and philosophy, the disciplines ($\mu\alpha\theta\eta\mu\alpha\tau\alpha$), and arithmetic, music, geometry, and astronomy, arts ($\tau\epsilon\chi\eta\mu\alpha\tau\alpha$) included under philosophy.

The distinction between the old and new meaning of mathematics is most requisite to be kept in mind, because arguments are frequently urged for and against mathematics, in which the discipline is confounded with the communication of facts and processes about space and number; and because it is our intention in the present article, confining ourselves to the most important view of the science, as well as to the etymological meaning of its name, to offer a few remarks on the discipline called mathematics.

— ARTS AND SCI. DIV. VOL. V.

In the time of Plato, which was probably that of the application of words which imply "the discipline" to that one exercise of mind which consists in making deductions by pure reasoning from the self-evident properties of space and number, it is probable that such restriction of the word was easily justifiable. At present we have, besides mathematics, also physics, the study of antiquity, grammar, &c., which have all been made disciplines, but not one of which was then entitled to that appellation. Nevertheless it has happened that writers, misled partly by the name of mathematics and partly by the pre-eminence of mathematical reasoning in strictness and connection, have spoken as if it were the *only* cultivator of the pure reasoning power.

Much discussion has arisen upon the question whether those primary propositions which, from our clear apprehension and willing admission of them, are called self-evident, are notions inherent in the mind, or deductions of early experience. Except to mention this controversy, we have here nothing to do with it. The certainty of these propositions is all that we want, and this is conceded by both sides. The consideration however of the fundamental supports of mathematical reasoning is useful and interesting, and, as a safeguard, even necessary. It is not long since a school of metaphysicians existed who imagined that because all mathematical definitions are precise, therefore the exact sciences are founded upon definition. It was not to them a necessary result of the constitution of our faculties that the three angles of every triangle make up the same amount, but a consequence of definition, which might have been something else, upon different suppositions. We can hardly undertake to explain what we do not understand: if the opinion we have quoted have not the meaning we have given to it, there is in it some confusion of terms. We recommend every beginner in the subject to seek no knowledge about the character of fundamental propositions until he shall have become well acquainted with their consequences. He must take care to admit nothing which is not, or cannot be made, most evidently true; and he will find that all axioms, as they are called, have the highest sort of certainty, namely, that they cannot be imagined otherwise.

Whatever may be the psychological hypothesis to which it is referred, it is certain that there is a real distinction between a mathematical fact and one of any other kind. If we say that an unsupported bit of lead will fall to the ground, we state a fact of which we are as certain, in the sense of reliance, as we are of the other proposition that two straight lines cannot inclose a space. But in the former proposition an exception, or even a permanent alteration of the law, is conceivable by the imagination: in the latter the mind would feel sensible of absurdity if it attempted to construct the idea of an inclosure bounded by only two straight lines. No distinctive phrases can be too strong to express the essential difference of these two assertions; but it is a misfortune that all terms which create a sufficient distinction are linked to one or another theory of the human mind. If the mathematical student can receive these terms as indicative of the difference of species, without bending before an hypothesis about the conformation of his own reason, he will do well to adopt them; if, on the other hand, he feel compelled to agree with any one system of mental philosophy, he will neither impede nor advance his mathematical career.

The unavoidable certainty and definite character of mathematical conclusions have obtained for mathematics the name of *exact science*: but to this name it has not exclusive right. The laws under which we must think are the foundation of a science which has an equal claim with mathematics to any epithet which indicates either necessity or precision. Accordingly logic and mathematics are separate branches of exact science. There are but three things of which we cannot divest ourselves so long as we imagine ourselves to retain both existence and consciousness of existence: they are thought, space, and time. With everything else there is a possibility of dispensing; that is, the imagination can conceive everything got rid of, and out of existence, except its own consciousness in some kind of activity, and the space and time without which it cannot conceive existence. The necessary laws of thought are the subject matter of logic: the necessary properties of space and time are the subject matter of mathematics. *Number* is an offspring of the notion of time; enumeration is a succession in time; in no other way can *number* be distinguished from *multitude*. And geometry is, without need of illustration, the offspring of the notion of space.

There has long been something of schism between the cultivators of logic and those of mathematics. To establish this fact, and to speculate on the reasons of it, would require more space than we have to give. The effect has been unfortunate. The mathematician dispenses with the analysis of the laws of thought; the logicians avoid that field in which the laws of thought are applied to necessary matter. This state of things is perhaps mending, but until the improvement is very decided, neither mathematics nor logic will be what they ought to be, as component parts of liberal education.

The sciences of which we speak may be considered either as disciplines of the mind, or as instruments in the investigation of nature and the advancement of the arts. In the former point of view their object is to strengthen the power of logical deduction by frequent examples; to give a view of the difference between reasoning on probable premises and on certain ones, by the construction of a body of results which in

M M

no case involve any of the uncertainty arising from the previous introduction of that which may be false; to form the habit of applying the attention closely to difficulties which can only be conquered by thought, and over which the victory is certain if the right means be used; to establish confidence in abstract reasoning by the exhibition of processes whose results may be verified in many different ways; to help in enabling the student to acquire correct notions and habits of generalisation; to give caution in receiving that which at first sight appears good reasoning; to instil a correct estimate of the powers of the mind, by pointing out the enormous extent of the consequences which may be developed out of a few of its most fundamental notions, and its incapacity to imagine, much less to attain, the boundary of knowledge; to methodise the invention of the means of expressing thought, and to make apparent the advantages of system and analogy in the formation of language and symbols; to sharpen the power of investigation, and the faculty of suggesting new combinations of the resources of thought; to enable the historical student to look at men of different races, opinions, and habits, in those parts of their minds where it might be supposed *a priori* that all would most nearly agree; and to give the luxury of pursuing a study in which self-interest cannot lay down premises nor deduce conclusions.

As instruments in the investigation of nature and the advancement of the arts it is the object of the mathematical sciences to give correct habits of judgment and ready means of expression in matters involving degree and magnitude of all kinds; to teach the method of decomposing phenomena, and ascending from the complicated forms of manifestation to the simple law which regulates them; to trace the necessary consequences of any law, assumed on suspicion, in order to compare those consequences with phenomena; to construct hypothetical representations of laws, or approximations to laws, which shall sufficiently represent phenomena; to convert processes of known accuracy, but complicated operation, into others which make up in simplicity for a certain amount of inaccuracy, and to devise means for judging of that amount of inaccuracy, and confining it within given limits; to ascertain the most probable result of observations or experiments which are discordant with each other from errors of measurement or unknown causes of disturbance; to point out the species of experiments which should be made to obtain a particular sort of information, or to decide between two laws which existing phenomena both indicate as of nearly equal credibility; to make all those investigations, which are necessary for the calculation of results to be used in practice, as in nautical astronomy, application of force and machinery, and conduct of money transactions; in a word, though that word by itself would have not presented a sufficiently precise idea, to find out truth in every matter in which nature is to be investigated, or her powers and those of the mind to be applied to the physical progress of the human race, or their advancement in the knowledge of the material creation.

The main branches of mathematical science were formerly stated to be arithmetic and geometry, springing out of the simple notions of number and space. This is too limited a description. Unquestionably the science of numbers, strictly and demonstratively treated, and that of geometry, or the deduction of the elementary properties of figure from definitions which are entirely exclusive of numerical considerations, must be considered as the elementary foundations, but not as the ultimate divisions, of mathematics. To them we must add the science of operation, or algebra in its widest sense,—the method of deducing from symbols which imply operations on magnitude, and which are to be used in a given manner, the consequences of the fundamental definitions. The leading idea of this science is operation or process, just as number is that of arithmetic, and space and figure of geometry: it is of a more abstract and refined character than the latter two, only because it does not immediately address itself to notions which are formed in the common routine of life. It is the most exact of the exact sciences, according to the idea of their exactness which is frequently entertained, being more nearly based upon definition than either arithmetic or geometry. It is true that the definitions must be such as to present results which admit of application to number, space, force, time, &c., or the science would be useless in mathematics, commonly so called; but it is not the less true that a system of methods of operation, based upon general definitions, and conducted by strict logic, may be made to apply either to arithmetic or geometry, according to the manner in which the generalities of the definition are afterwards made specific.

The common division of the mathematical sciences will not admit of the threefold separation just described, the science of operation being more or less mixed up with arithmetic, both in common algebra and in its application to geometry. We may describe this division as follows:—

1. *Pure Arithmetic*, subdivided into *particular* and *universal*:* the former, the common science of numbers (integral and fractional) and calculation; the latter, the science of numbers with general symbols, or the introduction to methods of operation, restricted to purely

* We have supplied the word *particular*, as opposed to *universal*; algebra was sometimes called *universal arithmetic*, but the phrase never became general, owing to its being obvious to those who studied algebra, that arithmetic, however general its symbols may be, is only a part of algebra.

numerical processes. The science which treats of the peculiar relations of numbers, and subdivides them into classes possessing distinct properties, is called the *theory of numbers*, and is an extension which frequently requires a higher algebra.

2. *Pure Geometry*, which investigates the properties of figures in the manner of Euclid, that is, with restrictions which confine the student to the straight line and circle as the means of operation and the boundaries of figure. [GEOMETRY.] This science includes solid geometry, as far as figures bounded by planes, the properties of the sphere, cone, and cylinder, and of their plane sections; but it does not allow any conic section, except the straight line and circle, to be employed in the solution of problems.

3. *Algebra*, including the general calculus of operations (though this is not an elementary branch), and all methods which can be established without the aid of processes exclusively belonging to the differential calculus. The distinction between it and universal arithmetic is an extended use of operations, preceded by an extended definition of their meaning.

4. *Application of Algebra to Geometry*.—This includes *trigonometry*, and all those parts of geometry in which problems are numerically solved, and the method of Euclid is abandoned. Thus it includes the conic sections as commonly taught; and in its higher parts is an application of the differential calculus, as well as of algebra.

5. *Differential and Integral Calculus*.—Under this term we include the general theory of limits; that is, all digested methods of operation, in which the limits of ratios are used as algebraical quantities under specific symbols. This distinction is necessary, since the notion of a limit, and even propositions which belong to the differential calculus in everything but form, are contained in the elements of Euclid, and in the application of arithmetic to geometry. The *calculus of differences* and the *calculus of variations* are usually placed under this head: the former, in its elementary parts, might be referred to common algebra; the latter is an extension of the differential calculus.

The division of the mathematical sciences into *pure* and *mixed* is convenient in some respects, though liable to lead to mistake. By the former term is understood arithmetic, geometry, and all the preceding list; by the latter, their application to the sciences which have matter for their subject, to mechanics, optics, &c. But considering that in all these subjects a few simple principles are the groundwork of the whole deduction, they might be explained as intended to answer two distinct questions: first, what are the consequences of such and such assumptions upon the constitution of matter? secondly, are these consequences found to be true of matter as it exists, and are the assumptions therefore to be also regarded as true? In the reply to the first question, the science is wholly mathematical; to the second, wholly experimental in its processes, and inductive in its reasonings; and this is the *mixture* from which the joint answer to both questions derives its name, and not from any difference between its mathematics and those of the pure sciences. Again, a science does not take the name of mixed mathematics simply because it is possible to apply mathematical aid in the furtherance of its legitimate conclusions: such a use of terms would be trifling with distinctions, since it would bring political economy, chemistry, geology, and almost every part of natural knowledge, under the same head as mechanics and hydrostatics. The words in question should be reserved to denote those branches of inquiry in which few and simple axioms are mathematically shown to be sufficient for the deduction, if not of all phenomena, at least of all which are most prominent. Taking the leading ideas of the mixed sciences instead of their technical names, we may describe them as relating to motion, pressure, resistance, cohesion, light, heat, sound, electricity, and magnetism. As disciplines, it is their main object to teach the true method of inquiry into the laws, and, so far as can be known, the causes, of material phenomena; as instruments, it is not necessary to say one word about them. Two only have not been mentioned: the first, astronomy, which belongs to more than one of the preceding; the second, the theory of probabilities, of which, though placed among the mixed sciences, it may be affirmed that it ought to be called an *application of mathematics to logic*.

The most important question connected with the mathematical sciences is the manner in which they should be taught as disciplines of the mind. This concerns all who consider any branch of knowledge in that light; and, as education spreads, this view of the subject will become of more and more consequence. Vitally essential as these sciences are to the advancement of the arts of life, we feel, in regard to this branch of their utility, in the situation of those who know that they must and will be attended to, because their cultivation is necessary to the supply of wants which all can feel, and the promotion of interests which all can understand. It is not so with the first-mentioned object of their study, but rather the reverse; for the wants of life being as easily supplied by the results of an illogical as of a logical system (provided only that vicious reasoning be not allowed to produce absolute falsehood), the facilities which laxity of reasoning affords in the mere attainment of results will always recommend it to those whose main object it is to apply the fruits of calculation to the uses of life. Such has been, and, we are afraid, will continue to be, the tendency of the great advance which the last century made in application.

All we should positively contend for is the necessity of making the

entrance to the study as strict and rigorous as reason can make it, to all who are to receive liberal education. In the higher branches of mathematics many opinions prevail, and it would be impossible to make a formal standard of rigour. Add to this, that, with a certain degree of experience in the estimation of reasoning, it may be comparatively immaterial which of several different methods is adopted; either may be rigorous if properly understood, and if the habit of reducing looseness of phraseology, or dangerous abbreviation of logic, to strict definition and formal deduction, shall first have been well formed. To assist in gaining this end, we should propose—

First, that no student should be allowed to enter upon the use of language in mathematical reasoning until he has acquired more acquaintance with the nature of assertion, denial, and deduction, than can be obtained from previous education as now given: this to be done by the study of the first elements of logic.

Secondly, that no consideration of facility or practical convenience should prevent the first study of arithmetic and geometry from being strictly demonstrative, and formally rigorous: rigour being defined to consist in explicit statement of every assumption, and logical treatment of every inference.

On the first of the preceding recommendations we shall only observe, that in order to distinguish between accurate and inaccurate inference, an acquaintance with the exact extent of meaning of the several modes of communication is absolutely necessary. This cannot be learnt from the ordinary use of language, which abounds in implications to be suggested by the circumstances of the speaker, the context of the words, or the tone in which they are delivered. Before the phrases of demonstration can be made to convey a meaning limited in both directions, the strict use of language must be made a study; if this be neglected, the words of any book may pass between the teacher and the learner, but no precaution has been taken to secure their conveying the proper meaning, neither too much nor too little.

On the second recommendation, we must first explain that we hold many points of controversy very cheap, so far as they concern the discipline given by the most elementary branches of mathematics. It matters nothing, in our view of the case, whether an axiom be really incapable of proof, or whether the substitution of another would or would not place the science on a more simple basis. The habit to be formed is that of tracing necessary consequences from given premises by elementary logical steps: the premises to be true or false, the consequences to be true if the premises be true, and dubious (not necessarily false) if the premises be false. The only error which, at the stage in question, it is intended to avoid, is the deduction, as a necessary consequence, of that which is not so. The mind of the learner, however, is allowed to dwell too much at the outset on the absolute truth or falsehood of the conclusions, to the neglect of their connection with the premises: hence it arises that when a process occurs in which it is essential to examine that connection for its own sake, it is the universal complaint that beginners find difficulty and obscurity. From what other cause arises the dislike of the indirect demonstration?

Unfortunately for the mental progress of the student, he is often allowed to use premises of an easy form, in cases where complete preparation for the subject would require more extended first principles and greater prolixity of deduction. To this, as before observed, no objection can be taken in itself, provided that no consequences be admitted except the legitimate ones. But something more is admitted: the pupil is presented, in consideration of his attention to one set of premises, with the consequences of another, and is allowed to make believe that he has come fairly by the latter. Thus, by a theory which applies only to the ratio of number to number, he is permitted to draw general conclusions upon all ratios. When, in opposition, we advise that the first studies should be demonstrative and rigorous, we do not imply, for instance, that the more difficult system should in all cases be preferred to the less complete but more simple: we confine ourselves to insisting that whatever the premises may be, the conclusions should really follow; and that if the latter be necessarily of a limited character the limitation should be stated.

The work of Euclid is preferable, in our opinion, to any system which has been proposed to supply its place; simply because the dependence of conclusions upon premises is more distinct than in any other geometrical writing. The defects with which it abounds are trifles which can be remedied as they are met with; and though there are seldom three propositions together one or other of which will not call for some remark from the teacher, yet such is Euclid, that these very faults, properly noted, are of more value than the greater elegance and more artificial process of less formally rigorous writers. Of the part relating to PROPORTION we shall treat under that word.

The necessity of a demonstrative system of arithmetic was practically denied, in this country at least, by the use of a set of dogmatical rules: and this mode of teaching is still too prevalent. Such training would be less prejudicial if the notions of the student on reasoning were more settled, so that he could receive these rules with some fitting idea of their purpose, and of the extent to which they are to be considered as knowledge. As it was, he had no other view of arithmetic presented to him, and his conceptions of number were allowed to be first fettered, and afterwards led astray, by ideas derived sometimes from the reception of the conventional for the necessary, sometimes from modifications of truth which are convenient in practice though unsound in theory.

Such an addition to his stock of mathematical power predisposed him to acquiesce in the shifts by which rigour is avoided in other parts of the science; and an arithmetic from which both sequence and accuracy of thought had been excluded was the asylum of geometry against truth, when the latter became too difficult for an unenergetic, that is untrained, power of investigation.

We shall conclude this article with some references to works on the history of mathematics, a subject so connected with that of the other sciences, that it would be impossible to say anything on it in few words. The great work of Montucla, continued (from his papers partly) by Lalande, '*Histoire des Mathématiques*,' 4 vols., Paris, 1799-1802, is the most accessible source of information for the reader who desires some detail. The bibliography of Murhard, '*Litteratur der Mathematischen Wissenschaften*,' Leipzig, 1797, will be found a useful accompaniment in the verification of dates. The work of Kästner, '*Geschichte der Mathematik*,' Göttingen, 1796, is more precise in its account of individual labours than that of Montucla, but does not embrace so large a field. The works of Bossut, namely, the preface to the mathematical part of the '*Encyclopédie Méthodique*,' and the '*Histoire des Mathématiques*,' 2 vols. 8vo., Paris, 1810, are written in an interesting manner; and the latter (which was translated by Bonycastle) brings some parts of the history later than its predecessors. Cossali's '*Origine dell' Algebra*,' 2 vols. 4to., Parma, 1799, is an account of the early Italian algebra: its successor in the same subject, '*Histoire des Sciences Mathématiques en Italie*,' Paris, 1838, by M. Libri (of which four volumes have appeared) has gained a character which places it among the first efforts of the kind. Much on the subjects of algebra, logarithms, and trigonometrical tables may be found in Dr. Hutton's Tracts (3 vols. 8vo., 1812), and in the preface of his Logarithms. The work of Montucla, '*Récherches sur la Quadrature du Cercle*,' reprinted with additions in 1831, is complete on the subject of which it treats. There is a work on a kindred subject which we have never seen, Reimer, '*Historia Problematis de Cubi Duplicatione*,' Göttingen, 1798. Delambre's '*Rapport Historique sur les Progrès des Mathématiques depuis 1789*,' Paris, 1810, is the least specific of his historical works, but, points of nationality apart, is accurate. Professor Peacock's article on arithmetic in the '*Encyclopædia Metropolitana*,' and his report on Analysis, in the second volume of the '*Transactions of the British Association*,' are full of historical information of the most precise character. Some notices of early English mathematicians, enough to guide the reader to sources of information, are contained in the '*Companion to the Almanac*' for 1837, and in the '*Magazine of popular Science*,' Nos. 18, 20, and 22 (a work completed in 4 vols. 8vo.). The eleventh volume of the '*Memoirs of the Academy of Brussels*' contains the '*Aperçu Historique*,' &c. of M. Chasles, a history of geometry and a complete account of its modern progress.

Among works of older date, which are often cited, we may notice Ward's '*Lives of the Gresham Professors*,' London, 1760; Heilbronner's '*Historia Matheseos Universæ*,' Leipzig, 1742, does not deserve that title, but contains an immense quantity of information on the ancient part; G. J. Vossius, '*De quatuor Artibus popularibus*,' Amsterdam, 1650, contains a large number of dates and short biographical accounts; to Blancanus, '*De Mathematicarum Naturâ Dissertatio*,' Bologna, 1615, is appended a chronological list of mathematicians up to the time of Galileo; the '*Scolæ Mathematicæ*' of Peter Ramus, Frankfurt, 1627, contains many historical notices. The number of writings which might be referred to as incidentally affording information is of course numerous.

MATHEMATICS, RECENT TERMINOLOGY IN. The terms intended to be explained in the present article relate to subjects distinct indeed, but intimately connected together, as well logically as historically. *Determinants* were devised as a means to the solution of a system of simple equations, but the principle of their construction is contained in the rule of signs which belongs to the theory of *arrangements* (or *permutations*): this theory has been studied, as well for its own sake, as in reference to the theory of equations, and in it originated the notion of a *group*, the most outlying term of those which are here explained. Moreover, in a system of simple equations, if the coefficients arranged in the natural square order are considered apart by themselves, this leads to the theory of *matrices*, a theory which indeed might have preceded that of determinants; the matrix is, so to speak, the matter of a determinant; the rule of signs giving the form. But when the rule of signs is applied to other matter, this leads to the functions called *permutants*; these include *commutants* and *intermutants*, and also *Pfaffians*, which however were not originally so arrived at. The theory of elimination (according to one of the two ways in which it may be treated) is essentially dependent upon systems of linear equations, and is thus also connected with determinants. And all, or nearly all, the before-mentioned theories have an application to the theory of rational and integral homogeneous functions, or, as they have been termed, *forms* or *quantics*; they are thus connected with the "*Calculus of Forms*," and with "*Quantics*;" the last-mentioned expression (used as a singular), has been defined to denote the entire subject of rational and integral functions, and of the equations and loci to which these give rise. The theory of rational and integral functions was first studied in a general manner in the question of *linear transformations*, and it was this question which led to the discovery of the functions, called originally *hyperdeterminants*,

but afterwards *invariants*, and of the more general functions called *covariants*: the theory of covariants is indeed the part which has been chiefly attended to of the Calculus of Forms, or of Quantics.

The following list of terms may be convenient:—

Rule of signs.
Group.
Determinant.
Minor,
Symmetric, skew, skew symmetric.
Commutant.
Pfaffian.
Permutant.
Intermutant.
Cumulant.
Matrix.
Resultant.
Discriminant.
Plexus.
Rational and integral functions (notation and nomenclature of).
Quantic, quadric, cubic, &c., binary, ternary, &c., facient, tantipartite, lineolinear.
Emanant.
Linear transformations.
Modulus of transformation, unimodular.
Hyperdeterminant.
Invariant.
Covariant.
Contravariant, peninvariant, seminvariant, quadrinvariant, quadricovariant, &c., catalecticant, canonisant.
Canonical form.
Bezoutic matrix, &c.
Tactinvariant, reciprocant.
Functional determinant, Jacobian, Hessian.
Concomitant, cogredient, contragredient.
Combinant.

RULE OF SIGNS.—Any arrangement of a series of terms may be derived (and that in a variety of ways) from any other arrangement by successive interchanges of two terms; but in whatever way this is done, the number of interchanges will be constantly even, or else constantly odd; and the two arrangements are said to be of the same sign or of contrary signs accordingly. In particular, if any arrangement is selected as the primitive arrangement, and taken to be positive, then any other arrangement will be positive or negative according as it is derivable from the primitive arrangement by an even or an odd number of interchanges. The definition leads to the following theorem: any arrangement is positive or negative, according as the total number of times in which the several elements respectively precede (mediately or immediately) elements posterior to them in the primitive arrangement, is even or odd: it may be added, that the positive and negative arrangements are equal in number. Thus in the case of three terms, the primitive arrangement being 123; the positive arrangements are 123, 231, 312, the negative arrangements, 132, 213, 321: in the case of four terms, the primitive arrangement being 1234, the arrangements 1234, 2341, 3412, 4123 are respectively positive, negative, positive, negative; there are in all twelve positive and twelve negative arrangements.

GROUP.—The term was originally used as applied to substitutions only, but the more general use of the term is as follows: let θ be a symbol operating on any number of terms $x, y, z, \dots$ and producing as the result of the operation the same number of new terms $x', y', z', \dots$ (where $x, y, z, \dots$ may be each of them functions of all or any of the set, $x, y, z, \dots$; if $x, y, z, \dots$ are merely the terms, $x, y, z, \dots$ in a different order, then θ is a substitution, which explains in what sense that term has just been used). Imagine a set of operative symbols, $1, \theta, \phi, \chi, \dots$ (1, as an operative symbol denotes, of course, a symbol which leaves the operand unaltered) such that the result of the operation of any two symbols θ, ϕ (the same or different, and if different, then in either order) is identical with that of the operation of some symbol χ of the set; as thus, $\theta\phi(x, y, z, \dots) = \theta(x, y, z, \dots) = (x', y', z', \dots) = \chi(x, y, z, \dots)$, say, $\theta\phi = \chi$; then the symbols $1, \theta, \phi, \chi, \dots$ form a *group*. It is to be remarked that 1 belongs to every group, and moreover, that if θ be any symbol of the group, then $\theta^2, \theta^3, \theta^4, \dots$ belong to the group: the most simple form of a group (and when the number of terms is prime, the only form) is $1, \theta, \theta^2, \dots, \theta^{n-1}$ [$\theta^n = 1$]. More generally, if there are n terms in the group, then every symbol θ of the group is an operation periodic of the order n (if not of an order a submultiple of n) and thus satisfies the symbolic equation $\theta^n = 1$. The symbols of the group are, so to speak, the symbolic n -th roots of unity, and as in the above-mentioned example, they may, whether n is prime or composite, form a system precisely analogous to that of the ordinary n -th roots of unity; but when n is composite, then upon two grounds this is not of necessity the case. 1°. The symbols of a group need not be convertible (thus $n=6$, there is a group, $1, \beta, \beta^2, \alpha, \alpha\beta, \alpha\beta^2$ [$\alpha^2=1, \beta^3=1, \beta\alpha=\alpha\beta^2$ and $\beta^2\alpha=\alpha\beta$, this is in fact, the group of the substitutions of three things]). 2°. There may be distinct n -th roots, thus $n=4$, there is a group, $1, \alpha, \beta, \alpha\beta$ [$\alpha^2=1, \beta^2=1, \alpha\beta=\beta\alpha$], in which α, β are distinct

square roots of (the symbolical) unity, and which is thus wholly different from the group, $1, \alpha, \alpha^2, \alpha^3$ [$\alpha^4=1$].

The combination of a series of terms in the way of addition or subtraction, according to the rule of signs, gives rise to the class of functions called *permutants*, which include as a particular but the earliest discovered and most important case, the *determinant*.

DETERMINANT.—Imagine a square arrangement of terms, for example—

$$\begin{vmatrix} a & b & c \\ a' & b' & c' \\ a'' & b'' & c'' \end{vmatrix}$$

and taking this as the primitive arrangement, permute in every possible way entire columns (or, what would give the same result, entire lines) and for each such arrangement form the product of the terms in the dexter diagonal (N.W. to S.E.) of the square, giving to such product the sign which belongs to the arrangement of the columns (or lines). The algebraical sum of these products is a determinant, and such determinant is, or may be represented as above, by inclosing the terms within two vertical lines. Thus the developed value of the determinant in question is

$$ab'c'' - ab''c' + a'b''c + a''b'c' - a''b'c - a'b''c$$

The rule may be otherwise stated as follows: a determinant is the sum of a series of products each with its proper sign, such that in each product the factors are taken out of each line and out of each column, and if the factors are arranged according to the primitive arrangement of the columns in which they occur, then the sign is that corresponding to the resulting arrangement of the lines (or *vice versa*); thus in the product $-a'b''c'$, the factors a, b'', c' occur in the columns 1, 2, 3 (they are therefore arranged according to the primitive arrangement of the columns) and in the lines 1, 3, 2. Such arrangement of the lines considered as derived from the primitive arrangement 1 2 3 is negative, and the product has therefore the sign $-$. A generalisation of this construction will be mentioned under the term *commutant*.

The word *resultant* was formerly used as synonymous with *determinant*, but it is now employed and is here explained in a more extended signification. The new synonym *eliminant* seems unnecessary.

A few of the numerous properties of determinants may be stated.

A determinant is a linear function (without constant term) of the terms in each of its columns, and also of the terms in each of its lines, or, more briefly expressed, it is a linear function of each column, and also of each line. Moreover, without altering the value of the determinant, the lines may be made columns, and the columns lines, and all the properties of the function exist equally with respect to the lines and with respect to the columns. The absolute value of the determinant is not altered, but the sign is reversed, by an interchange of two columns, hence also if two columns become identical, the determinant vanishes. Moreover when the columns are permuted in any manner whatever, the absolute value is not altered, but the sign will be that corresponding to the arrangement of the columns. A determinant may be developed as a linear function of the terms in any line, thus—

$$\begin{vmatrix} a & b \\ a' & b' \end{vmatrix} = a | b' | - a' | b | ,$$

$$\begin{vmatrix} a & b & c \\ a' & b' & c' \\ a'' & b'' & c'' \end{vmatrix} = a \begin{vmatrix} b' & c' \\ b'' & c'' \end{vmatrix} + b \begin{vmatrix} c' & a' \\ c'' & a'' \end{vmatrix} + c \begin{vmatrix} a' & b' \\ a'' & b'' \end{vmatrix} ,$$

the signs being alternately positive and negative or else all positive, according as the number of columns is even or odd.

The square arrangement of terms out of which a determinant is formed, and generally any square or rectangular arrangement of terms, is called a *matrix*. Consider a determinant.

$$\begin{vmatrix} a & b & c & d \\ a' & b' & c' & d' \\ a'' & b'' & c'' & d'' \\ a''' & b''' & c''' & d''' \end{vmatrix}$$

and partitioning the lines in any manner, form with them the matrices

$$\begin{vmatrix} a & b & c & d \\ a' & b' & c' & d' \end{vmatrix} , \quad \begin{vmatrix} a'' & b'' & c'' & d'' \\ a''' & b''' & c''' & d''' \end{vmatrix} ,$$

and out of these matrices, with complementary columns thereof, a sum of products

$$\pm \begin{vmatrix} a & b \\ a' & b' \end{vmatrix} \begin{vmatrix} c'' & d'' \\ c''' & d''' \end{vmatrix} ,$$

(the sign $\pm$ being that corresponding to the product $a'b'c''d'''$ of the terms in the dexter diagonals of the factor determinants, considered as a term of the original determinant), the sum of all the products so obtained is the original determinant.

It has been mentioned that the determinant is a linear function of each column; hence if the terms of any column are $pa, pa', \dots$ the determinant is equal to p times a determinant in which the corresponding column is $a, a', \dots$ and similarly if the column is $a + b, a' + b', \dots$ then the determinant is the sum of two other determinants in which the corresponding columns are $a, a', \dots$ and $b, b', \dots$ respectively.

This property, in combination with some of those already mentioned, leads very simply to the rule for the multiplication of determinants; for example, we have

$$\begin{vmatrix} \rho, & \sigma \\ \rho', & \sigma' \end{vmatrix} \begin{vmatrix} \alpha, & \beta \\ \alpha', & \beta' \end{vmatrix} = \begin{vmatrix} \rho\alpha + \sigma\beta, & \rho'\alpha + \sigma'\beta \\ \rho'\alpha + \sigma'\beta, & \rho'\alpha + \sigma'\beta \end{vmatrix},$$

from which the law is obvious. The product might also be expressed, and although it appears less simple, there is an advantage in expressing it, in the form

$$\begin{vmatrix} \rho\alpha + \sigma\alpha', & \rho\beta + \sigma\beta' \\ \rho'\alpha + \sigma'\alpha', & \rho'\beta + \sigma'\beta' \end{vmatrix}.$$

If we omit simultaneously any line and any column of a determinant, and with the terms which are left form a determinant, the determinants so obtained are the *first minors* of the given determinant. A similar process, but omitting pairs, triads, &c. of lines and columns, gives the *second minors*, *third minors*, &c. of the given determinant. But the first minors are the most important, and are sometimes spoken of simply as the minors.

A determinant

$$\begin{vmatrix} a, h, g \dots \\ h, b, f \\ g, f, c \\ \vdots \end{vmatrix} \quad \text{or} \quad \begin{vmatrix} 11, 12 \dots \\ 21, 22 \\ \vdots \end{vmatrix},$$

where the corresponding terms on opposite sides of the dexter diagonal are equal to each other (say $rs = sr$) is said to be *symmetrical*.

But if the terms are equal in magnitude only, but have opposite signs (say $rs = -sr$, this relation not extending to the terms in the diagonal, for which $s = r$) the determinant is said to be *skew*; and if the relation extends to the case $s = r$, or what is the same thing, if the terms in the diagonal vanish, the determinant is said to be *skew symmetrical*. Skew determinants have an intimate connection with the functions called Pfaffians.

COMMUTANT.—The second rule for the construction of a determinant might have been thus stated, viz. for the determinant

$$\begin{vmatrix} 11, 12 \dots 1n \\ 21, 22 \\ \vdots \\ n1 \end{vmatrix}$$

write down the expression

$$\begin{matrix} 11 \\ 22 \\ \vdots \\ nn \end{matrix}$$

and permute in every possible way the numbers in the first column, prefixing in each case the sign of the arrangement. Then reading off

$$\begin{matrix} \pm r1 \\ s2 \\ \vdots \\ zn \end{matrix}$$

as meaning

$$\pm y1 \cdot s2 \dots zn$$

the sum of all the terms so obtained is in fact the determinant in question. The same result would be obtained by permuting the numbers in the second column instead of those in the first column. And moreover, if the numbers in both columns are permuted, the sign being the sign $\pm$ compounded of the signs corresponding to the separate arrangements, the only difference is, that the determinant will be multiplied by the numerical factor $1 \cdot 2 \cdot 3 \dots n$.

If instead of two we have three or more columns, the resulting function is a *commutant*. But a distinction is to be made according as the number of columns is even or odd. In the former case we may permute all but one of the columns, and it is indifferent which column is left unpermuted; and if all the columns are permuted, the effect is merely to introduce the numerical factor $1 \cdot 2 \cdot 3 \dots n$. In the latter case, if all the columns are permuted, the result is zero, and it is therefore essential that one column should remain unpermuted; moreover, different results are obtained according to the column which is left unpermuted, and such column must therefore be distinguished; this is done by placing above it the mark $\dagger$.

PAFFIAN.—Suppose that the terms $12, 13, 21$, &c., are such that $21 = -12$, and generally that $sr = -rs$, then the Pfaffians $1234, 123456$, &c., are defined by means of the equations

$$\begin{aligned} 1234 &= 12 \cdot 34 + 13 \cdot 42 + 14 \cdot 23, \\ 123456 &= 12 \cdot 3456 + 13 \cdot 4562 + 14 \cdot 5623 + 15 \cdot 6234 + 16 \cdot 2345, \\ &\text{(where of course } 3456 = 34 \cdot 56 + 35 \cdot 64 + 36 \cdot 45, \text{ and so for } \\ &\quad 4562, \text{ \&c.)} \end{aligned}$$

and so on. The functions in question occur in the solution of an important problem (including that of partial differential equations of the first order and of any degree) known as Pfaff's problem, and were named accordingly.

It may be noticed that a skew symmetrical determinant of any odd order is equal to zero; but that a skew symmetrical determinant of any

even order is the square of a Pfaffian, e.g. if $12 = -21$, &c., as above, then

$$\begin{vmatrix} 0, 12, 13, 14 \\ 21, 0, 23, 24 \\ 31, 32, 0, 34 \\ 41, 42, 43, 0 \end{vmatrix} = (12 \cdot 34 + 13 \cdot 42 + 14 \cdot 23)^2.$$

PERMUTANT.—A very simple instance of a permutant is as follows, viz.: V_{123}, V_{213} , &c., being any quantities whatever, then the permutant $((V_{123}))$ denotes the sum

$$V_{123} + V_{231} + V_{312} - V_{132} - V_{213} - V_{321}$$

and in like manner for any number of permutable suffixes, or if instead of a single set of permutable suffixes we have two or more sets of such suffixes. It will be at once obvious how a permutant includes a determinant, commutant, or Pfaffian; thus, if V_{123} denotes $a_1 b_2 c_3$ and therefore $V_{213} = a_2 b_1 c_3$, &c., then we have a determinant, so if V_{123} denotes $a_{12} a_{34}$ where $a_{21} = -a_{12}$, &c., we have a Pfaffian.

INTERMUTANT is a special form of permutant which need not be here further explained.

CUMULANT.—The name has been given to the function which is the numerator or denominator of a continued fraction. Such function may be exhibited (and indeed naturally presents itself) in the form of a determinant, thus the cumulant $(abcd)$ or numerator of the fractions $a + \frac{1}{b + \frac{1}{c + \frac{1}{d}}}$ is

$$\begin{vmatrix} a, & 1, & \cdot, & \cdot \\ -1, & b, & 1, & \cdot \\ \cdot, & -1, & c, & 1 \\ \cdot, & \cdot, & -1, & d \end{vmatrix},$$

and so for a greater number of terms. The developed expression is $abcd + ab + ad + bc + 1$, which is formed from the produced $abcd$ by successively omitting each product (cd, bc, ab) , or set of products (cd, ab) of two consecutive letters; in like manner the cumulant $(abcde)$ is $abcde + abc + abe + ade + a + c + e$.

MATRIX.—The term might be used to denote any arrangement of terms, but in a restricted sense it denotes a square or rectangular arrangement of terms, and it is thus employed in the theory of determinants.

To show further how the notion of a matrix is made use of, it may be remarked that a system of linear equations

$$\begin{aligned} \xi &= a x + b y + c z, \\ \eta &= a' x + b' y + c' z, \\ \zeta &= a'' x + b'' y + c'' z \end{aligned}$$

is in the notation of matrices represented by

$$(\xi, \eta, \zeta) = \begin{pmatrix} a, & b, & c \\ a', & b', & c' \\ a'', & b'', & c'' \end{pmatrix} (x, y, z)$$

The corresponding set of equations which give (x, y, z) in terms of (ξ, η, ζ) is represented by,

$$(x, y, z) = \begin{pmatrix} a, & b, & c \\ a', & b', & c' \\ a'', & b'', & c'' \end{pmatrix}^{-1} (\xi, \eta, \zeta)$$

and we have thus the definition of the *inverse* or *reciprocal* matrix: it follows from the theory of determinants that the terms of the reciprocal matrix are the first minor determinants formed out of the original matrix, each of them divided by the determinant formed out of the original matrix; but in writing down the expression some attention is required with respect to the arrangement and signs of the terms.

Similar considerations lead to the notion of *multiplying* or *compounding* together two or more matrices. As an instance of such composition, take

$$\begin{pmatrix} \rho, & \sigma \\ \rho', & \sigma' \end{pmatrix} \begin{pmatrix} \alpha, & \beta \\ \alpha', & \beta' \end{pmatrix} = \begin{pmatrix} \rho\alpha + \sigma\alpha', & \rho\beta + \sigma\beta' \\ \rho'\alpha + \sigma'\alpha', & \rho'\beta + \sigma'\beta' \end{pmatrix}$$

where it is to be observed that the lines of the first or *further* component matrix are compounded with the columns of the second or *nearer* component matrix to form the lines of the compound matrix. The words *further*, *nearer*, are used in reference to a set (x, y) which is, or may be considered to be, understood at the right of each side of the equation. A matrix may be compounded with itself once or oftener, giving rise to a positive power of such matrix; the notion of the negative powers is deducible from that of the inverse or reciprocal matrix, and the same process of generalisation as is employed for powers of a single quantity leads to the notion of the fractional powers of a matrix. As a definition of *addition*, matrices are added together by the addition of their corresponding terms, and as a particular case of the multiplication or composition of matrices we have the multiplication of a matrix by a single quantity, effected by multiplying by such quantity each term of the matrix; all these notions together lead to the notion of *functions* of a matrix.

As an instance of the employment of the notation of matrices for another purpose, take

$$\begin{pmatrix} a, & b, & c \\ a', & b', & c' \\ a'', & b'', & c'' \end{pmatrix} (x, y, z) (\xi, \eta, \zeta),$$

used to denote the lineo-linear function

$$\begin{aligned} & (ax + by + cz)\xi \\ & + (a'x + b'y + c'z)\eta \\ & + (a''x + b''y + c''z)\zeta \end{aligned}$$

which includes

$$\begin{pmatrix} a, & h, & g \\ h, & b, & f \\ g, & f, & c \end{pmatrix} (x, y, z)^2,$$

used to denote the quadric function

$$ax^2 + by^2 + cz^2 + 2fyz + 2gzx + 2hxy.$$

The last preceding notation is an instance of a *symmetrical* matrix: the terms *skew*, *skew symmetrical*, already explained with respect to determinants, apply also to matrices.

RESULTANT.—If there be a system of equations between the same number of unknown quantities (it is assumed that the several equations are of the form $U=0$, where U is a rational and integral homogeneous function), then the function of the coefficients which equated to zero expresses the result of the elimination of the unknown quantities from the several equations, or (what is the same thing) gives the condition for the existence of a set of values satisfying the equations simultaneously—is the *Resultant* of the equations, or of the functions which are thereby put equal to zero. In the case of two (non-homogeneous) equations involving a single unknown quantity, we may say more briefly that the resultant is the function which equated to zero gives the condition for the existence of a common root. In the particular case of a system of linear equations between as many unknown quantities, the resultant is the determinant formed with the coefficients of the equations.

DISCRIMINANT.—If in a system of equations the functions equated to zero are the derived functions of a single rational and integral homogeneous function with respect to each of the variables thereof, the resultant of the system is said to be the *discriminant* of the single function. The definition is easily made applicable to the case of a non-homogeneous function, the functions equated to zero are here the function itself and its derived functions with respect to each of the several variables. For a single function, it may be said that the discriminant is the function which equated to zero gives the condition for a pair of equal roots of the equation obtained by putting the function equal to zero.

To fix the precise value of the discriminant of a given function, it is assumed that the coefficient of some one selected term is +1. Thus, the discriminant of $ax^2 + 2bxy + cy^2$ is $a^2c - b^2$: that of $ax^3 + 3bx^2y + 3cxy^2 + dy^3$ is $a^2d^2 - 6abcd + 4ac^3 + 4b^3d - 3b^2c^2$.

In quadratic forms (in the theory of numbers) the expression $b^2 - ac$, which is the determinant $\begin{vmatrix} a, & b \\ b, & c \end{vmatrix}$ with the sign reversed, is called the determinant of the form $ax^2 + 2bxy + cy^2$. And in like manner for ternary quadratic forms, there is the same reversal of sign. It may be said as a convenient definition, that the determinant is the discriminant taken negatively.

PLEXUS.—It frequently happens, in problems of elimination and in other problems, that a given number of relations existing between a system of quantities can only be completely expressed by means of a greater number of equations. Thus, to take a very simple instance, if the unknown quantities x, y , are to be eliminated between the three equations $ax + by = 0$, $a'x + b'y = 0$, $a''x + b''y = 0$: this implies two relations between the coefficients a, b, a', b', a'', b'' ; but these relations cannot be completely expressed otherwise than by means of the three equations $ab' - a'b = 0$, $a'b'' - a''b' = 0$, $a''b - a'b'' = 0$; for taking any two of these equations, e.g. the first and second, these would be satisfied by $a' = 0$, $b' = 0$, which however do not satisfy the third equation and are not a solution. Such a system of equations, or generally the system of equations required for the complete expression of the relations existing between a set of quantities (and which are in general more numerous than the relations themselves) is said to be a *Plexus*.

RATIONAL AND INTEGRAL FUNCTIONS (*Notation and Nomenclature of*).—A rational and integral homogeneous function, such as the function $ax^2 + 2bxy + cy^2$ is denoted by—

$$(*) (x, y)^2$$

where the coefficients are only indicated by the asterisk, but are not expressed. A non-homogeneous rational and integral function is considered as derived from a homogeneous function by putting one of the variables thereof equal to unity, and is represented accordingly: thus $ax^2 + 2bx + c$ is denoted by

$$(*) (x, 1)^2.$$

But it is often proper to express the coefficients, and in regard to this the following distinction is made, namely—

$$(a, b, c) (x, y)^2$$

denotes $ax^2 + 2bxy + cy^2$; and in like manner $(a, b, c, d) (x, y)^3$ denotes $ax^3 + 3bx^2y + 3cxy^2 + dy^3$, &c., the numerical coefficients being those of the successive powers of a binomial. But when such numerical coefficients are not to be inserted, this is denoted by an arrowhead, or other distinctive mark; thus $(a, b, c)^\dagger (x, y)^2$ denotes $ax^2 + bxy + cy^2$. A rational and integral function of any order is termed a *quantic*, and a function of the orders two, three, four, five, &c., is termed a *quadric*, *cubic*, *quartic*, *quintic*, &c., respectively. The number of variables (the function being homogeneous) is denoted by the words *binary*, *ternary*, &c. As a correlative term to coefficients, the variables have been termed *facients*. A function which is linear in respect to several distinct sets of variables separately is said to be *tantipartite*: or, when there are two sets only, *lineo-linear*. Thus a determinant is a tantipartite function of the lines or of the columns; the function $axx' + bxy' + cxy + dyy'$ is a lineo-linear function of (x, y) and (x', y') ; a notation for it is

$$\begin{pmatrix} a, & b \\ a', & b' \end{pmatrix} (x, y) (x', y')$$

such as has been spoken of in regard to matrices.

EMANANT.—The development of an expression such as

$$(*) (\lambda x + \mu x', \lambda y + \mu y')^m$$

is naturally written under the form

$$\begin{aligned} & (*) (x, y)^m \quad \lambda^m \\ & + \frac{m}{1} (*) (x, y)^{m-1} (x', y') \lambda^{m-1} \mu \\ & + \quad \vdots \quad \\ & + (*) (x', y')^m \quad \mu^m, \end{aligned}$$

and the coefficients of the successive terms $\lambda^m, \lambda^{m-1}\mu$, &c., are said to be the *emanants* of the quantic $(*) (x, y)^m$. The coefficients of λ^m , or 0-th emanant, is the quantic itself, and the coefficient of μ^m , or ultimate emanant, is the quantic with (x', y') in the place of (x, y) ; but the intermediate emanants are functions of (x, y) and (x', y') homogeneous in respect to the two sets separately. The coefficients may of course be expressed thus, the emanant (first emanant) of $(a, b, c) (x, y)^2$ is $(a, b, c) (x, y) (x', y')$, which stands for $axx' + b(xy' + x'y) + cy^2y'$.

LINEAR TRANSFORMATIONS.—In this theory the variables of a function are supposed to be respectively linear functions of a new set of variables, so that the function is transformed into a similar function of these new variables, with of course altered values of the coefficients, and the question was to find the relations which existed between the original and new coefficients and the coefficients of the linear equations. The determinant composed of the coefficients of the linear equations is said to be the *modulus of transformation*, and when this determinant is unity the transformation is said to be *unimodular*. It was observed that a certain function of the coefficients, namely, the discriminant, possessed a remarkable property, found afterwards to belong to it as one of a class of functions called originally *hyperdeterminants*, but now *invariants*, and it was in this manner that the problem of linear transformation led to the general theory of covariants.

INVARIANT.—An invariant is a function of the coefficients of a rational and integral homogeneous function or quantic, the characteristic property whereof is as follows: namely, if a linear transformation is effected on the quantic, then the new value of the invariant is to a factor *près* equal to the original value; the factor in question (or quotient of the two values) being a power of the modulus of transformation, and the two values being thus equal when the transformation is unimodular. The easiest example is afforded by the quadric function $(a, b, c) (x, y)^2$; effecting upon it a linear transformation, suppose that we have identically

$$(a, b, c) (ax' + \beta y', \gamma x' + \delta y')^2 = (a', b', c') (x', y')^2$$

then it may be easily verified that $a'c' - b'^2 = (a\delta - \beta\gamma)^2 (ac - b^2)$. The invariant $ac - b^2$ is however in this case nothing else than the discriminant; as another example take the quartic $(a, b, c, d, e) (x, y)^4$, for which $a^2e - 4bd^2 + 3c^2$, $ace - a^2d^2 - b^2d^2 + 2bcd - c^3$ are functions possessed of the like property of remaining to a factor *près* unaltered by the transformation, and are consequently invariants; it may be added that calling them I, J , respectively, the discriminant is here $= I^3 - 27J^2$, a rational and integral function of invariants of a lower degree.

COVARIANT.—Instead of a function of the coefficients only, we may have a function of the coefficients and variables, possessed of the like property of remaining unaltered to a factor *près* by the linear transformation: such function is termed a *covariant*. Thus, a covariant (the Hessian) of the quartic $(a, b, c, d, e) (x, y)^4$ is

$$(ac - b^2, 2ad - 2bc, ae + 2bd - 3c^2, 2be - 2cd, ce - d^2) (x, y)^4.$$

The quantic itself is one of its own covariants. The term covariant may be used in contradistinction to, or as including, invariant. The terms invariant, covariant, have been explained in reference to the simple case of a single quantic containing but one set of variables, but they apply equally to the case of a system of quantics, and to quantics which are homogeneous functions of two or more distinct sets of variables. There is one case which it is proper to mention: if in con-

junction with a quantic $(*) (x, y, z \dots)^m$ we consider a linear function $\xi x + \eta y + \zeta z + \dots$, the invariants of the system are functions of the coefficients of the quantic, and of the coefficients $\xi, \eta, \zeta \dots$ of the linear function; and treating these as facients, the invariant is said to be a *contravariant* of the given quantic.

The foregoing definition gives the characteristic property of a covariant, but it does not directly show how the covariants of a given quantic are to be investigated. This is supplied as follows:—For any quantic with arbitrary coefficients, for example $(a, b, c, d)(x, y)^4$, there exist operators involving differentiations in respect to the coefficients, tantamount to the operators $x d_y$ and $y d_x$ in respect to the variables; thus the operator $a d_b + 2 b d_c + 3 c d_d$ is tantamount to $y d_x$, and $3 b d_a + 2 b d_c + c d_d$ is tantamount to $x d_y$. Or what is the same thing, denoting for shortness these operators by $\{y d_x\}, \{x d_y\}$ respectively, the quantic is reduced to zero by each of the operators $\{y d_x\} - y d_x, \{x d_y\} - x d_y$. Any function of the coefficients and the variables which, in like manner with the quantic itself, is reduced to zero by these two operators respectively, is said to be a *covariant*; or, if it contains the coefficients only, an *invariant* of the quantic. That the two definitions lead to the same result is of course a theorem to be proved.

The leading coefficient of a covariant, say the coefficient of x^m in any covariant of a binary quantic $(*) (x, y)^m$, possesses the property of being reduced to zero by the operator $\{y d_x\}$, and has been termed a *peninvariant*, but a more appropriate term is *seminvariant*. An invariant is a function of a given degree in the coefficients, and a covariant is a function of a given degree in the coefficients and order in the variables, and they may be and are designated accordingly; thus, the above-mentioned invariants 1, 5 of a binary quartic are called respectively the *quadrinvariant* and the *cubinvariant*, and the covariant of the same quartic is termed the *quadricovariant*, or if the distinction were required it would be termed the *quadricovariant quartic*. In these cases the designations are sufficient, but it is to be noticed that in general there is more than one invariant or covariant of the same degree or of the same degree and order, and that any such designation is only a generic, not a specific, name. An invariant or covariant may also be designated by a name referring to the mode of generation—for example, the discriminant. The name *catalecticant* denotes a certain invariant of a binary quantic of an even order: namely, it is a determinant, which, for the above-mentioned quartic function, is—

$$\begin{vmatrix} a, b, c \\ b, c, d \\ c, d, e \end{vmatrix}$$

(being in this particular case the cubinvariant), and the name *canonisant* denotes a certain covariant of a binary quantic of an odd order, namely, it is a determinant the terms whereof are linear functions of the coefficients, and which for the cubic $(a, b, c, d)(x, y)^3$ is

$$\begin{vmatrix} ax + by, bx + cy \\ bx + cy, cx + dy \end{vmatrix},$$

(being for the particular case the Hessian or quadricovariant).

CANONICAL FORMS.—A binary quantic of an odd order $2m+1$ admits of being expressed as a sum of $(m+1)$ powers of linear functions, for example, the cubic $(a, b, c, d)(x, y)^3$ can be expressed in the form $(lx + my)^3 + (l'x + m'y)^3$ —this is the *canonical form* of a binary function of an odd order. And there is in like manner a form (not admitting, however, of a simple definition) which is taken as the *canonical form* of a binary quantic of an even order. The *catalecticant* and the *canonisant* present themselves in the problem of the reduction of a binary quantic to the canonical form.

BEZOUTIC MATRIX.—If v, w are any two binary quantics of the same order m , v', w' are what v, w become when the variables (x, y) of the two quantics are changed into (x', y') ; then $(v w' - v' w) \div (x y' - x' y)$ is a rational and integral homogeneous function of the degree $m-1$ in each of the two sets $(x, y), (x', y')$, and the coefficients taken in their natural square arrangement constitute the Bezoutic matrix. The determinant formed out of this matrix is in fact the resultant of the two functions, or equated to zero it is the equation obtained by the elimination of the variables from the two equations $v=0, w=0$. If v, w are the derived functions of one and the same binary quantic of the order m , then the corresponding matrix, being of course of the order $(m-2)$, is the Bezoutoidal matrix, and the determinant is then the discriminant of the single quantic.

It would be too long to explain the allied terms Bezoutiant, Cobezoutiants, Bezoutoid, Cobezoutoids.

TACTINVARIANT, RECIPROCAN.—A definition in the language of analytical geometry will be the most easily intelligible, and it can readily be converted into an analytical form and made applicable to any number of variables. The function of the coefficients which equated to zero expresses that the two curves $u=0, v=0$, touch each other, is an invariant, namely, it is the *tactinvariant* of the two functions u, v . And in particular, if, instead of the curve $v=0$, we have the line $\xi x + \eta y + \lambda z = 0$, then the function which equated to zero expresses that this line touches the curve $u=0$, is a *contravariant*, namely, it is the *reciprocant* of the function u .

FUNCTIONAL DETERMINANT, JACOBIAN, HESSIAN.—If v, w be quantics, then the determinant—

$$\begin{vmatrix} d_x v, d_y v, \dots \\ d_x w, d_y w, \dots \\ \vdots \end{vmatrix}$$

is the functional determinant, or Jacobian, of the quanties $v, w \dots$. And if $v, w, \dots$ are the derived functions of $d_x u, d_y u, \dots$ of one and the same quantic u , then the determinant in question is the *Hessian* of the single quantic: the Hessian is in fact to the Jacobian what the discriminant is to the resultant.

CONCOMITANT, COGREDIENT, CONTRAGREDIENT.—The theory of linear transformations has been considered from a different point of view; instead of the variables of a function being put equal to linear functions of a new set of variables, they are considered as being replaced by a new set of variables, linear functions of the original variables. Two sets of variables may be so related that when the first set is thus replaced by a set of linear functions of themselves, the second set is also replaced by a set of linear functions of themselves, the co-efficients of the two sets of linear functions being related together in a definite manner; this is *concomitance*, or rather it is (what is alone here spoken of) *simple concomitance*. The two most important kinds of concomitance are, 1st. *Cogredience*, that is, when the substitution on the second set of variables is identical with that upon the first set; 2nd. *Contragredience*, that is, when the substitution on the second set of variables is the inverse or reciprocal one to that on the first set; it will make the notion of contragredience clearer to remark that if the variables $x, y, \dots$ and $\xi, \eta, \dots$ are contragredients, then $x', y' \dots$ (which are linear functions of $x, y \dots$) and $\xi', \eta' \dots$ (which are linear functions of $\xi, \eta \dots$) are so related that $\xi' x' + \eta' y' + \dots = \xi x + \eta y + \dots$. It was from the consideration of contragredient variables that the notion of a contravariant was first derived, but as above remarked, the notion is really included in that of a covariant.

COMBINANT.—A combinant is a covariant (or invariant) of a set of quantics of the same order, which, besides being a covariant in the ordinary sense of the word, is, so to speak, a covariant *quoad* the system, that is, it remains to a factor *près* unaltered, when the quantics of the system are replaced by linear functions of themselves; the factor in question being a power of the determinant formed with the coefficients of the linear functions. For instance, if $u = (a, b, c)(x, y)^2$ and $v = (a', b', c')(x, y)^2$, then $ac' - 2bb' + ca'$ is a function which, when for the original coefficients are substituted those of $\lambda u + \mu v, \nu u + \rho v$, is merely changed into $(\lambda \rho - \mu \nu)^2 (ac' - 2bb' + ca')$, and it is therefore a combinant. It would appear that the notion of a combinant might be extended to the case of a system of quantics not of the same order, and that the resultant of the system of quantics could be brought under the extended definition of a combinant, but this is a point which has not been considered.

The principal text-books on the foregoing subjects, are—on determinants:—Spottiswoode's 'Elementary Theorems relating to Determinants,' 4to, London, 1851; Brioschi, 'Teoria dei Determinanti,' 4to, Pavia, 1854, translated into French by Combescure and into German by Schellbach; Baltzer, 'Ueber die Determinanten,' 8vo, Leipzig, 1857 (especially valuable for its references to the original sources). On elimination: Faà de Bruno, 'Theorie générale de l'élimination,' 8vo, Paris, 1859. And extending to nearly all the subjects: Salmon, 'Lessons introductory to the modern higher Algebra,' 8vo, Dublin, 1859. The memoirs on the different subjects are very numerous, and it was not thought expedient to give a list of them.

MATICA or MATICO, Medical Properties of. This name is applied to an astringent plant brought from Peru, where it has long enjoyed a high reputation for its styptic properties. Doubts exist as to the botanical origin of the plant, some ascribing it to a Labiate plant, resembling a *phlomis*, while others refer it to a piperaceous plant, and even assert that it is the *piper angustifolium* (Ruiz et Pavon, tab. 64, a), a native of Peru. By Miguel this plant is now referred to the genus *Artanthe*, separated from *Piper*, and is called *Artanthe elongata*. It is a *Steffensia*, according to Kunth (in *Linnaea*, xiii. 609). The odour of the leaves, somewhat resembling a *mentha*, and the large quantity of volatile oil obtained from them, lend countenance to the opinion of its being a labiate plant; while the alternate position of the leaves in most of the specimens described entirely negatives this notion. The probability is, that two distinct plants pass under the name of Matico, which, though they have a distinct origin, have similar properties. Frequent instances of this are found in Brazil, where numerous plants are called *caa-peba*; and several, reputed antidotes to the bites of serpents, are all termed *quaco*: one of these is the *Eupatorium glutinosum*, Kunth. The analysis of the leaves seems to have been made on the piperaceous plant, which is stated to yield a drink employed by the Indians to produce effects similar to the bang obtained from the *Cannabis Indica*. Matico has been analysed by Dr. Hodges, who found it to contain, 1, chlorophylle; 2, a soft dark-green resin; 3, a brown colouring matter; 4, a yellow colouring matter; 5, gum, and nitrate of potash; 6, a bitter principle, *Maticine*; 7, an aromatic volatile oil; 8, salts; 9, lignin.

Cold water extracts, in about four hours, all the medicinal virtues of the plant, and is an eligible means of administering it. A tincture is also employed, and the powdered leaves are both given internally and

applied externally. It does not owe its astringent properties to tannin: and it seems to exert a vital action on bleeding vessels, so as speedily to arrest the hæmorrhage. It has been used to check other discharges, such as the profuse expectoration and also the night-sweats of consumptive patients. Few drugs exert more than a temporary influence over these symptoms; but among such, Matico seems well entitled to attention. Still more potent is oxide of zinc in such cases.

MATICIN. A non-azotised bitter principle, of unknown composition, found in the leaves of the *Artanthe elongata*.

MATINS (from the Italian *matina*, or the French *matin*, morning), strictly the first part in the daily service of the Romish church. Matins or mattins however were divided into two parts, which were originally distinct offices and hours; namely, the *nocturn and matin lauds*. The *nocturns* or vigils were derived from the earliest period of Christianity. We learn from Pliny the younger, as well as from Justin Martyr, Tertullian, and various writers of the first three centuries, that the Christians in those times of persecution held their assemblies in the night, in order to avoid detection. On these occasions they celebrated the memory of Christ's death in the holy mysteries. When persecution had intermitted and finally ceased, although the Christians were able to celebrate all their rites, and did administer the sacrament in the day-time, yet a custom which had commenced from necessity was retained from devotion and choice; and nocturnal assemblies for the worship of God in psalmody and reading still continued. The monastic orders, which, in the 4th century, arose under Pachomius, Anthony, Basil, and others, in Egypt, Pontus, and Syria, tended to preserve this custom of nocturnal vigils; and in the following centuries we find, from the testimony of Cassianus, Augustine, and others, that the same custom remained in most parts of the East and West. In the 6th century Benedict, the great founder of monastic societies in the West, prescribed the same in his Rule; and nocturnal assemblies were common about that time, especially in monasteries. The *lauds*, or more properly *matin lauds*, followed next after the nocturns, and were supposed to begin with day-break. We find allusions in the writings of Cyprian, and all the subsequent fathers, to the morning as an hour of prayer; but whether there was in the 3rd century any assembly of the church for the purpose of public morning worship is uncertain. However, about the end of the third or beginning of the 4th century there was public worship at this hour, as we learn from the 'Apostolical Constitutions,' where we have the order of the service.

(Bingham's *Antiquities of the Christian Church*, b. xiii.; Palmer's *Origines Liturgicæ*.)

MATRASS, a glass chemical vessel, employed for the purpose of digesting, boiling, and distillation, and sometimes, while one is used as the body, another serves as the receiver in the last-mentioned operation. Florence flasks are very commonly used for these purposes, and they answer admirably, on account of the excellent nature of the glass, which is such as to resist the effects of sudden alterations of temperature. Sometimes matrasses are very conveniently formed with flat bottoms, instead of their being round as in oil-flasks.

MATRIX, or **GANGUE**. Metallic ores are seldom found unmixed in the places in which they occur; they not only accompany each other, but are frequently associated with useless stony bodies, and these are called the matrix, or gangue.

It also happens that ores in some cases become gangues with relation to more precious minerals; those which may be distinguished as metallic gangues are iron pyrites, spathose iron-ore, oxide of iron, hydrate of iron, and blende; the earthy gangues are usually quartz, felspar, limestone, carbonate of baryta, sulphate of lime, sulphate of baryta, and fluor-spar.

MATRONS, JURY OF. When a widow alleges herself to be with child by her late husband, and it is suspected that she is not pregnant, or not so by the husband, a writ de ventre inspiciendo may be obtained out of chancery, on behalf of the next heir, whose rights might be prejudiced by a supposititious, or spurious, child. Under this writ a jury of "discreet and lawful women" is impanelled, to try, by inspection of her person (et ubera et ventrem tractando), whether the widow is with child or not, and if with child, to inquire of the time of conception, and of that of the expected delivery. If the widow be found to be pregnant, the sheriff, on returning the writ, certifies the court of common pleas to this effect; whereupon the widow, unless she be remarried (in which case she is not to be taken from her husband), is to be kept in a castle, or other safe place, until her delivery, in order, as far as possible, to prevent any child being improperly introduced as the issue of the husband, to the disinheritance of the heir. (Bracton, lib. 2, cap. 32; Croke, Eliz., 566; 6 Vesey, 260; 21 Viner's 'Abr.', 547.)

In the parliament roll of 9 Edw. II. (1 'Rot. Parl.' 353, 354), is a curious proceeding, instituted on the 13th July, 1315, by the sisters and coheirs of Gilbert de Clare, earl of Gloucester, who had died on the 30th June, 1314, to recover their inheritance out of the king's hands, notwithstanding the alleged pregnancy of the countess, his widow. At the parliament held in January following, (more than eighteen months after the death of the earl), the king's sergeants insisted that it was still the duty of the crown to retain possession of the estate for the benefit of the expected offspring, whose birth had from natural causes (permittente natura) been so long deferred; and

it was not until Easter term, 1316, that the impediment was treated as removed.

A jury of matrons is also summoned to inquire into the fact of pregnancy in cases where a woman convicted of treason or felony, upon sentence of death being pronounced, pleads, in stay of execution, that she is with child. If the matrons impanelled to try this allegation find it to be true, the convict, whether she be married or unmarried, is respited until after her delivery. In some of the cases reported, the matrons have been directed to inquire whether the convict is *quick* with child; in other cases, and those by far more numerous, the inquiry seems to have been general, namely, *pregnant* or not pregnant. (Hawkins 'P. C.', book ii., cap. 51, sec. 9.) As the child is now known to have the same degree of foetal life before as after the change of position which occasions the sensation called quickening, the latter form of the inquiry appears to be not only the more humane but also the more correct; more especially as the law has now rejected the distinction between quick and not quick, in cases of attempts to procure abortion. (7 Will. IV. & 1 Vict., c. 85, s. 6.) After delivery the convict is not to be executed without an award of execution by the court. But when called upon to say why execution should not be awarded against her, the convict cannot plead that she is again with child; such further pregnancy being considered not to be a sufficient ground for suspending, for a second time, the execution of the sentence. The jailor is, under such circumstances, punishable for his negligence. But if the ground of the first postponement was the preservation of the infant, there seems to be no reason why the life of the second child should be sacrificed. 'Blackst. Com.' by Christian, vol. iv. p. 395; by Kerr, iv. p. 465.

The form of proceeding where a woman alleges herself to be with child by her late husband, which is described in the passage of Bracton already referred to, is evidently taken from the Roman form of proceeding in a similar case, as described in 'Dig.' 25, tit. 4, "De Inspiciendo Ventre, custodiendoque Partu."

MATTER is the name given to every thing which is not mind. Such seems to be the only way of defining the word; and though the definition may appear to assume that mind is not matter, the contrary of which has been contended by the class of writers called materialists [MATERIALISM], yet it does not really do so. For whatever theory may be adopted as to the nature of mind, whether it be considered as a separate principle from matter, or merely as a different manifestation of the same principle, the word *mind* is indifferently retained; and our definition may consequently be at once reconciled with the materialist theory by paraphrasing it thus:—matter is the name given to the substance composing the universe, under all its different modifications, excepting only that one which is known by the name of mind.

Matter then is the name for that out of which all objects external to the mind are thought to be composed, the question being reserved, whether the mind is or is not composed of the same substance. What this substance is, to which the name of matter is given, we do not know, and have no means of knowing. Various speculations have been made as to its nature, and theories formed concerning the manner of its composition; but these have no better basis than conjecture. Other speculations have been made as to whether there is such a thing as matter or not; and some philosophers have seen in the solid world around us nothing but a creation of the mind. [BERKELEY, in BIOG. DIV.; IDEALISM.]

There is no need to enter here into any of these speculations. It is sufficient to know and say that man, subject to certain affections of his senses, is led to assign those affections to an external cause. This external cause is that which he calls matter. What this matter is in itself he knows not. He knows only its capability of producing in him certain affections, the ordinary affections of the five senses (sensations as they are called), and those which give the ideas of extension and resistance. Thus, having already supposed something without, he pronounces these to be qualities of that something; ignorant all the while what that something is, and knowing it only as the *substratum* of the qualities.

MATTHEW, ST., THE GOSPEL OF, is a canonical book of the New Testament, ascribed by the unanimous consent of the early Christian writers to the apostle Matthew.

It is not easy to determine the language in which this gospel was composed. That it was written in Hebrew (by which we are to understand the Syro-Chaldaic dialect spoken in Palestine in the time of Christ), and that it was composed for the Jewish Christians, is asserted by Papias (Eusebius, 'Hist. Ecc.', iii. 39), Irenæus (*Ibid.*, v. 8), Origen (*Ibid.*, vi., 25), Eusebius (*Ibid.*, iii. 24), and Jerome ('Comment. in Matt.', præf., and 'De Vir. Illust.', c. 3); and their account is followed by others of the early Christian writers. On the other hand it is argued in favour of a Greek original that these testimonies are inconclusive, for that Papias was a weak and credulous man, and that the other writers merely followed his account; that we find no traces of the actual existence of the Hebrew Gospel of St. Matthew, for all the quotations in the works of the early fathers are made from the Greek copy which we now have; that explanations are introduced which would be useless to Jewish readers (see Matt., i. 23; xxvii. 33-46); that parallel passages of the Old Testament are generally quoted from the Septuagint; and that the Greek Gospel which we now have bears every mark of being not a translation but an original document. In

order to reconcile these facts with the statements of the early writers, Bengel long ago, and others since, have supposed that there were two originals of the Gospel, one written in Hebrew for the Jewish converts, and the other in Greek for general use. This belief is gaining ground, and is supported by the facts that Greek was the common language of literature and business, and that Josephus wrote his history in both languages.

The date of St. Matthew's Gospel has been the subject of as much dispute as its original language. If it were written at first for the use of the Christians in Judæa, the date would probably be early; and it has been remarked that the exhortations which it contains to patience under persecution would be most acceptable to the Jewish Christians in their persecution by the Sanhedrim soon after the ascension of Christ. None of the early writers, except Irenæus, give any explicit testimony on the subject, but their statements appear to imply that this was the first written of the four Gospels, and also, what indeed Eusebius expressly asserts, that it was composed before Matthew left Judæa. On these grounds, and from the supposed improbability of the Christians remaining long without some written account of the life of Jesus, the general opinion has assigned it the date of about A.D. 41.

But Irenæus says that it was put forth while Peter and Paul were preaching at Rome and laying the foundations of a church there. ('Adv. Hær.,' iii. 1, in Euseb., 'Hist. Ecc.,' v. 8.) On the strength of this testimony Michaelis, Lardner, and others have fixed the date at A.D. 61 or 63, and Lardner has drawn an elaborate argument in favour of this date from the internal evidence of the book itself, in which he endeavours to show that Matthew understood many points in the Christian system which the Apostles did not understand till some considerable time after Christ's ascension. But as in these passages Matthew is recording the words and actions of Jesus, and not his own opinions, we cannot see any force in the argument.

Some of the advocates for a double original refer the Hebrew copy to the earlier date, and the Greek to the later.

The genuineness, authenticity, and canonical authority of this Gospel are established beyond dispute by the unanimous testimony of Christian writers from the earliest age, and by its place in the ancient versions. But many critics have doubted the genuineness of the first and second chapters, chiefly on account of the difference between the genealogy of Christ in the first chapter, and that given by St. Luke (iii.), and other discrepancies between these chapters and Luke's account of the early life of Christ, and other internal difficulties, and also on the ground that they were omitted in the copies used by the Nazarenes and Ebionites, which however were undoubtedly corrupt. The chief arguments on the other side are, that these chapters are contained in all the ancient MSS. and versions, that they are referred to and quoted by several of the Fathers, that the particle δὲ at the beginning of the third chapter shows that something had gone before, and that the style of these two chapters agrees with that of the rest of the Gospel, especially in the manner of quoting the prophecies of the Old Testament.

St. Matthew was an Apostle and an eye-witness of the acts of Jesus, at least of those which were after his call. His narrative has therefore the highest degree of credibility. His style of narration is simple and effective, and he relates the discourses of Christ with clearness, and often with great energy.

(Lardner's *Credibility and Lives of the Apostles and Evangelists*; Cave's *Lives of the Apostles*; Kuinoel, *Comment. in Lib. Hist. N. T. Proleg. in Matt.*; Dr. Kitto's *Introduction to St. Matthew*, in *Pictorial Bible*, edit. 1849; and the *Introductions* of Michaelis, Eichhorn, De Wette, Hug, and Horne.)

MAUNDY THURSDAY, the Thursday preceding Easter, on which the king or queen distributes alms to a certain number of poor persons at Whitehall; so named from the *maunds*, or baskets, in which the gifts were formerly contained. It was also called Shere Thursday, as we read in the 'Festival' of 1511; because anciently "people would that day shere theyr hedes and clypp theyr berdes, and so make them honest agenst Easter-day."

The custom of the maundy is of considerable antiquity. Augustine, according to Du Cange, is first quoted for it. It was a charitable custom, and instituted in imitation of our Saviour's pattern of humility. Originally the bestower of the maund also washed the feet of a certain number of the recipients of the charity. This ceremony is still continued by the Pope in Rome. In England at least it was not entirely confined to royalty. In the earl of Northumberland's 'Household Book,' begun in 1512, fol. 354, we have an enumeration of "Al maner of things yerly yeven by my lorde of his maundy, ande my laidis, and his lordshippi's childeren."

James II. was the last of our kings who performed the ceremony of washing the feet in person. The queen's royal alms are now distributed on Saturday at the almonry office, to the maundy men and women placed on the supernumerary lists, owing to the difference of the ages between the late king and her present Majesty. Both men and women receive 2*l.* 10*s.*, and as many silver pennies as the queen has numbered years. To the men, woollen and linen clothing, shoes, and stockings are given; and to the women, in lieu of clothing, 1*l.* 15*s.* each. The maundy men and women also receive 1*l.* 10*s.*, a commutation instead of the provisions heretofore distributed.

ARTS AND SCI. DIV. VOL. V.

Dr. E. D. Clarke, in his 'Travels in Russia,' 4to. Cambr., 1810, gives an account of the ceremonial of washing the feet of the apostles, as it is called, on this day at Moscow. "This," he says, "we also witnessed. The priests appeared in their most gorgeous apparel. Twelve monks, designed to represent the twelve apostles, were placed in a semicircle before the archbishop. The ceremony is performed in the cathedral, which is crowded with spectators. The archbishop performing all, and much more than is related of our Saviour in the 13th chapter of St. John, takes off his robes, girds up his loins with a towel, and proceeds to wash the feet of them all until he comes to the representative of St. Peter, who rises, and the same interlocution takes place as between our Saviour and that apostle."

(Brand's *Popular Antiq.*, edit. by Sir H. Ellis, 1841; Fosbrooke's *Encyclopædia of Antiquities*, p. 702.)

MAUR, ST., CONGREGATION OF, a celebrated society of Benedictines in France, who professed to follow the primitive rule of that order. It was first established in 1618. Pope Gregory XV., at the instance of Louis XIII., gave it his approval by his brief dated 17th May, 1621; and Urban VIII. granted it new privileges by a bull dated 21st January, 1627. The report of the sanctity of this congregation induced several bishops, abbots, and monks to submit their monasteries to the direction of its superior, so that the congregation at last became divided into six provinces, of which each contained about twenty religious houses. The most considerable were, St. Denys, St. Germain-des-Prés, St. Remi at Rheims, Marmoustier, St. Pierre de Corbie, Fleuri or St. Benoit sur Loire, Fescamp, and the Trinité de Vendôme. The monks, beside the rule of St. Benedict, had other particular statutes and constitutions, and were governed by a general-superior, assistants, and visitors, who held a general chapter every three years at Marmoustier. Those who have any acquaintance with the history and progress of learning in Europe will readily acknowledge the advantages which letters have derived from this famous congregation, whose researches took in the whole circle of sciences, philosophy excepted. Among its more eminent members in the 17th century may be enumerated Hugh Menard, Luc d'Acheri, Jean Mabillon, Thierri Ruinart, and Bernard de Montfaucon. Moreri gives a list of the general-superiors of this congregation from 1630 to 1756.

(Moréri, *Diction. Historique*, tom. vii.; *Histoire Littéraire de la Congregation de Saint Maur*, 1770, by Dom Tassin.)

MAUSOLEUM, is the general term applied to a sepulchral edifice. Originally, however, Mausoleum (*Μαυσόλειον*) designated the magnificent structure erected at Halicarnassus, B.C. 352, by Artemisia, as the sepulchre of her husband, Mausolus, king of Caria. So far did this surpass in magnificence all similar structures, that in the time of Pausanias, mausoleum had come to be the generic term for a costly tomb. Recent researches have invested the Mausoleum of Halicarnassus with a new interest.

Pliny gives a somewhat minute description of the building (xxxvi., 5), from which it appears to have been oblong in plan, the north and south sides extending 63 feet, the ends or fronts being shorter. The *pteron* was, he says, surrounded by thirty-six lofty columns, above which, and of equal height, rose by steps a pyramidal roof, the apex of which was surmounted with a quadriga. The entire height was 140 feet: the entire circuit 411 feet. Pythis and Satyrus were the architects. The sculptures with which it was adorned were the work of Scopas, Bryaxis, Timotheus, and Leochares, each of whom executed the frieze of one of the sides: the quadriga being the work of Pythis. All the ancient writers who refer to it do so in terms of unbounded admiration; and in the time of Pliny, and for centuries after, it was regarded as one of the "wonders of the world." Gradually, however, it appears to have become ruinous; in part at least it was probably thrown down by an earthquake, and its destruction was nearly completed when, in 1404, the Knights of Rhodes took possession of Halicarnassus and employed the materials of the Mausoleum in the erection of the castle, or fortress, of San Pietro. Twice, within little more than a century, was the castle repaired or enlarged, the Mausoleum still serving as a quarry; yet until the last occasion (1522) a large portion of the lower part of the building, including much of the sculpture, must have remained standing, as it is particularly described (from the narrative of one De la Tourrette who was present at its final destruction) in the 'Funerailles des Romains, Grecs, &c.,' of Guichard (Lyon, 1581, as quoted by Messrs. Newton and Hawkins). Eventually Halicarnassus passed into the hands of the Turks, who gave to the place the name of the castle, which they corrupted into Budrum, and the very site of the famous sepulchre was forgotten. Archaeologists, indeed, at various times, published their conjectures, and travellers once and again visited the spot in the hope of verifying them; but until within the last few years all was uncertainty.

The researches of Sir Charles Fellows in Asia Minor having called attention once more to the subject, the English government directed their ambassador at Constantinople, Sir Stratford Canning, if possible to secure the sculptures still existing in the Castle of Budrum from further injury; and he, having obtained a firman from the Sultan, caused them to be carefully removed and forwarded to the British Museum. They consisted of two or three mutilated statues and eleven slabs, which proved to be a portion of the frieze described by Pliny as containing the Amazonomachia, or Battle of the Amazons with the Greeks, a work of exceeding interest in the history of Greek art. Mr. C.

T. Newton, an assistant in the Department of Antiquities of the British Museum, now thoroughly reinvestigated the whole subject, and published the result of his inquiries in a paper which appeared in the 'Classical Museum,' vol. v. (1847). Later Mr. Newton visited Budrum, and having submitted a proposition for exploring the site of the Mausoleum which met with the approval of the government, he was appointed vice-consul at Mitylene; a firman was obtained from the Porte, empowering him to make the requisite excavations, and the English government (the Earl of Clarendon being then Foreign Secretary) supplied him with a ship-of-war, a body of sappers, an officer of engineers, and an accomplished architect as assistants, together with every requisite for the successful prosecution of the undertaking. The remarkable results of the explorations, so far beyond what the most sanguine had anticipated, have been published in the "Papers respecting the excavations at Budrum," presented to Parliament in 1858-59, and in various literary journals and proceedings of societies; but a more ample, thoroughly digested, and fully illustrated work on the subject, by Mr. Newton and Mr. Pullan, the architect associated with him, is announced as ready for publication. To that we must refer for further information. Here it will be enough to say that after one or two essays in the place commonly supposed to be the site of the Mausoleum, Mr. Newton commenced working on a spot indicated by Professor Donaldson, and soon found that he had come upon the actual site. The explorations were necessarily long and tedious. Mr. Newton had to purchase and remove several houses, to employ a large number of native hands, and to exercise great caution in his dealing with the Turkish authorities. But his labour was well repaid.

He found statues, bassi-relievi, columns, and other architectural features, all broken and fragmentary, and all heaped confusedly together; but all were patiently collected, sorted, and sent to England. Here by the skilful experts of the British Museum they were thoroughly examined, and in many instances from among the disconnected fragments whole figures have been with rare dexterity pieced together. Chief of these was the master-work,—a draped statue, 10 feet high, of Mausolus himself, which was in more than sixty pieces, and which were successively picked out, identified, and fitted together into perhaps the noblest work of its class in existence; while the relievi with those already in the Museum form an entire length of upwards of 80 feet of frieze, also in its way unrivalled. With these marbles thus diligently classified and arranged, and the explorations of Mr. Newton on the site, so much has now been discovered that not only has the actual site been identified beyond possibility of dispute, but the extent, dimensions, and character of the entire edifice have been so clearly elucidated, that, when one or two points are agreed upon, the architect will be able to restore as completely the Mausoleum of Halicarnassus as any other of the great buildings of antiquity.

A few words will show the results actually obtained. Mr. Newton having fortunately struck early upon an angle of the building was able to work down to the marble floor of its original foundation, and to trace the outline of its boundary walls. Hyginus mentions that the Mausoleum stood within a *peribolus*, or sacred enclosure, 1340 feet in circumference. This enclosure Mr. Newton found, and though, from part of the ground being occupied by buildings, he could not trace it throughout its extent, he was able to determine that instead of being oblong, as was supposed, it was a square, the sides of which were 337 feet, and that the Mausoleum occupied nearly the centre of the quadrangle. The foundations of the Mausoleum—which appear to have been laid on the site of a quarry which had been used as a cemetery—proved to be 126 feet by 107. The basement, the interior of which was built of a kind of green-ragstone, was 65 feet high and 112 feet long by 93 feet wide—making very nearly Pliny's 411 feet "totus circuitus." Its sides were decorated with the friezes (perhaps in two tiers) spoken of by Pliny. The peristyle consisted of thirty-six Ionic columns, which by the drums of the shafts, or frusta, it was ascertained were within an inch or two of the height named by Pliny (37½ feet, or 25 cubits). These columns surrounded a *cella* or temple (the *pteron* of Pliny) which was 63 feet by 46 feet: on the long sides were eleven columns, on the fronts nine—the actual space between the columns being exactly the same (7' 4") "as in the Temple of Minerva at Priene, which in other respects bears a great resemblance to the Mausoleum, was built about the same period, and not improbably by the same architect." (Newton). As to the remarkable pyramid described as rising above this *pteron*, Mr. Newton found a number of marble blocks or tiles, 2 or 3 feet broad, but of a uniform depth of 11¼ inches, and having on the upper side a groove, on the lower a flange, so as to joint firmly into each other. Twenty-four of these, with the quadriga and figures on the apex, make up almost exactly the 37½ feet of the ancient description. These blocks, however, when protracted, as shown in the restoration of Mr. Newton and Lieut. Smith, render necessary a space of 22½ feet from the centres of the columns to the walls of the *cella* in order to allow adequate extension to the base of the pyramid. This, besides the unusual extent to be borne without visible means of support—and which presents a great constructive difficulty—gave so flat a pyramid as to have a somewhat ungraceful appearance; and Mr. Fergusson has accordingly very acutely suggested that the pyramid instead of having the usual flat sides was curvilinear in outline, like the roofs of the Lycian tombs. This would afford a better outline and seem to suit better Pliny's resemblance of the

Pyramidal roof to a meta; but it has its difficulties, and the point must be regarded as at present unsettled: in other respects there does not seem to be much difference of opinion. Mr. Pullan, however, who supposes that by the *pteron* Pliny intended the peristyle and not the *cella*, believes that he shall be able, in Mr. Newton's forthcoming work, to put forth a restoration that will satisfactorily meet the various difficulties. The core of the basement, as we have seen, was of green-ragstone; but all that was visible of the entire building was of marble—coloured, however, as Mr. Newton thinks, from the traces he discovered, with the brightest blue and vermillion. Altogether, this very remarkable resuscitation has abundantly confirmed the statements of ancient writers as to the surpassing beauty and splendour of this unique edifice.

The vast collection of fragments of the Mausoleum brought to this country, is as present placed in a temporary enclosure under the portico of the British Museum, and not yet open to the public inspection. They comprise, as we said, a very large quantity of miscellaneous architectural fragments of great interest to the architect and archaeologist, and many valuable sculptural remains. These last include portrait statues of Mausolus and Artemisia—probably the most ancient examples of Greek portrait-statuary yet discovered, and very admirable as works of art. There are besides a colossal seated female figure, a male torso, and fragments of several other statues. Of equal interest with the Mausolus, but in another way, are the portions of two of the horses of the quadriga, which are larger in scale (they stood 10 feet high) than any other ancient marble horse yet discovered, and (allowing for the altitude at which they were placed) hardly inferior in style to the famous horses of the Parthenon; while the interest attached to them is not a little increased by the head retaining its original bronze bridle and accoutrements—the only instance known of this kind of decoration (though often referred to in ancient writing) which has come down to the present time. Another important fragment is that of the body of a horse and the torso of its rider, of colossal size, and of the most admirable design. Of the frieze, altogether 80 feet in extent, it is said by Mr. Newton that "no museum can show so magnificent a series of high reliefs." Besides these, there are six figures of lions in very tolerable preservation, and several fragments of lions, and broken portions of the frieze.

The Mausoleum erected at Babylon by Alexander the Great, in honour of Hephæstion, appears to have been equally magnificent with that at Halicarnassus, but less refined, and indeed somewhat extravagant in its decorations, as far as can be gathered from the account given of it by Diodorus (xvii. 115). It was adorned below by the gilded rostra, or beaks, of two hundred and forty ships, and every successive tier or story was enriched with a profusion of sculpture representing various animals, fighting centaurs, and other figures, all of which were gilt; and on the summit were statues of sirens, made hollow, in order that the singers who chanted the funeral dirge might be concealed within them.

The Mausoleums of Augustus and Hadrian at Rome were structures of great magnitude and grandeur, and resembled each other in being circular in plan. The first stood in the Campus Martius, where remains of it yet exist in the two concentric circles forming the first and second stories of the building, and the vaulted chambers between, which supported the first or lowest terrace. Of these terraces there were three; consequently four stages in the building, gradually decreasing in diameter, the uppermost of which was crowned by a colossal statue of the emperor. The terraces themselves were planted with trees.]

Hadrian's Mausoleum, now converted into the Castello di S. Angelo, in which shape it is familiar to almost every one, is a work of massive construction, and originally presented an unbroken circular mass of building, erected upon a larger square basement, lofty in itself, yet of moderate height in proportion to the superstructure, the latter being about twice as high as the former. This nearly solid rotunda, which was originally coated with white marble, had on its summit numerous fine statues, which were broken to pieces and the fragments hurled down by the soldiers of Belisarius upon the Goths, who attempted to take the building by storm. Neither are any remains now left of the uppermost stage of the edifice, which assumed the form of a circular *pteron* temple, whose diameter was about one-third of the larger circle. According to tradition, its peristyle consisted of the twenty-four beautiful marble Corinthian columns which afterwards decorated the Basilica of San Paolo fuori delle Mura; and its tholus or dome was surmounted by a colossal pine-apple in bronze, now placed in the gardens of the Vatican.

Such places as Henry VII.'s Chapel and the Pantheon of the Escorial may also be considered as mausoleums; but the term is generally restricted to a detached edifice erected merely as a private burying-place or to contain tombs. There are several structures of the kind in the parks of our nobility; among the more remarkable is that at Castle Howard, the seat of the Earl of Carlisle, and one of Hawksmoor's best works, a circular edifice in the Roman-Doric style, elevated upon a basement, and crowned by a dome: plans, sections, &c., of this structure have been beautifully engraved by Moses. The Marquis of Rockingham's mausoleum by Carr is another ornamental structure of the kind, composed of three stories, Doric, Ionic, and

Corinthian. We may also mention those at Cobham in Kent, and Brocklesby in Lincolnshire, by the late James Wyatt.

MAUVE. A new lilac colour or dye, obtained from aniline by Mr. Perkin. [COLOURING MATTERS.]

MAXIMA and MINIMA. These Latin words, which simply mean "greatest" and "least," are used to imply, not the absolute greatest and least values of a varying quantity, but the values which it has at the moment when it ceases to increase and begins to decrease, or *vice versa*. Thus, if it be said that the height of the barometer was a maximum at ten o'clock, it means that up to that hour the barometer rose, and then began to fall; in which case it would still be said to have been a maximum, even though it should afterwards rise, and stand at a greater height than that at ten o'clock. Thus it is possible that there should be several maxima and minima in one day, and even that one of the minima should be greater than one of the maxima; that is, at one moment when the fall ceases and a rise begins, the barometer may then be higher than it was at another time when a rise had ceased and a fall began.

The theory of maxima and minima is, mathematically speaking, very simple. It is obvious, from the definition of a differential coefficient, that if y be a function of x , and if x be increasing, then when y also increases, $\frac{dy}{dx}$ is positive; and when y diminishes, $\frac{dy}{dx}$ is negative. If the words increase and diminution have their full algebraical sense, this proposition is true whatever the sign of y may be.

It follows that when increase ceases and diminution begins, $\frac{dy}{dx}$ changes from positive to negative, and when diminution ceases and increase begins, it changes from negative to positive. But as a quantity cannot change its sign without becoming either nothing or infinite, it follows, first, that y can only be a maximum when x has such a value that $\frac{dy}{dx}$ is nothing or infinite; secondly, that there is not then a maximum unless the latter change from positive to negative, when x increases through that value; nor a minimum unless the same differential coefficient change from negative to positive, in the same case.

Thus when $y = a + x - x^2$, the differential coefficient of which is $1 - 2x$, we see that the latter changes sign when x changes from less than $\frac{1}{2}$ to greater than $\frac{1}{2}$; and the change of sign is from positive to negative. There is therefore a maximum when $x = \frac{1}{2}$, and this maximum is $a + \frac{1}{2} - \frac{1}{4}$, or $a + \frac{1}{4}$.

When $\frac{dy}{dx} = 0$ (which is by far the most common case), and there is a maximum, it changes sign from $+$ to $-$, or diminishes, algebraically speaking: therefore $\frac{d^2y}{dx^2}$ is negative. Similarly, when $\frac{dy}{dx} = 0$, and there is a minimum, $\frac{d^2y}{dx^2}$ is positive. But when $\frac{dy}{dx}$ is infinite, and there is a maximum or minimum, this additional rule does not apply.

Works on the differential calculus give the development of this theory and examples. We shall here only add one of the rules for determining the maximum or minimum when there are two distinct variables.

When z is a function both of x and y , two variables independent of one another, there may be a maximum or minimum when $\frac{dz}{dx}$ and $\frac{dz}{dy}$ are both nothing, both infinite, or one nothing and the other infinite. When they are both nothing, which is the only case in which this theory is of any practical application, it must be determined as follows whether there be any maximum or minimum, and which it is. Find the values of x and y which make $\frac{dz}{dx} = 0$, $\frac{dz}{dy} = 0$, and with any pair of these values find the value of the expression

$$\left(\frac{d^2z}{dx dy}\right)^2 - \frac{d^2z}{dx^2} \cdot \frac{d^2z}{dy^2}.$$

If this be negative, or nothing, there is a maximum or minimum; if it be positive, there is a mixture of the two which can only be satisfactorily explained by illustrations drawn from the theory of curved surfaces. When the expression is negative or nothing, there is a maximum if $\frac{d^2z}{dx^2}$ and $\frac{d^2z}{dy^2}$ be both negative, and a minimum if they be both positive.

The usual method of establishing all the preceding formulæ, namely, by the application of Taylor's theorem, applies only to the cases in which the differential coefficients become nothing, and not to that in which they become infinite. It is also frequently stated that there is always a maximum or minimum when a differential coefficient vanishes, which is not true.

MAXIMUM IN MACHINES. [MACHINE.]

MAY, the fifth month of our present year, was the second in the old Alban calendar, the third in that of Romulus, and the fifth in the calendar of Numa Pompilius. In the Alban calendar it consisted of twenty-two days; of thirty-one in the calendar of Romulus; and of thirty in that of Numa. Julius Cæsar restored to it the odd day of

which Numa had deprived it, and of which it still keeps possession; Its etymology is doubtful. Ovid, in the fifth book of his 'Fasti,' proposes three derivations: one from *majestas*; another from *majores*, a term which signified the *patres*, or governing body of the city of Romulus; and the third from *Maia*. The Roman month was under the protection of Apollo; and on account of the celebration of the Lemuria, marriages undertaken during its course were considered ill-omened. (Ovid, *Fasti*, v. 483-490.)

Our Saxon ancestors, after the Romans, called it *Maiusmonth*; and, in their native language, *threo-meolce*, three-milk month, when cows were milked three times a day.

MAY-DAY and MAYING. It was anciently the custom, observes Brand, for all ranks of people to go out a-maying early on the 1st of May. Bourne ('Antiq. Vulg.', ch. xxv.) tells us that, in his time, in the villages in the north of England, the juvenile part of both sexes were wont to rise a little after midnight on the morning of that day, and walk to some neighbouring wood, accompanied with music and the blowing of horns, where they broke down branches from the trees, and adorned them with nosegays and crowns of flowers. This done, they returned homeward with their booty about the time of sunrise, and made their doors and windows triumph in the flowery spoil.

There was a time when this custom was observed by noble and royal personages as well as the vulgar. Chaucer, Shakspeare, Browne ('Britannia's Pastorals'), and other writers in verse and prose, have described or alluded to the popular celebration of the day. The may-pole was raised in every town and village, and milk-maids and morris-dancers danced round it. These customs gradually fell into disuse; and in London the celebration of the day was left to the chimney-sweepers, whose representatives still in London and its suburbs struggle for an existence with their Jack-in-the-green and their tawdry finery. In many country villages, however, the observance of May-day is kept up on a small scale, by children carrying from door to door garlands of pails (or cowslips), blue-bells, and other field flowers; and in some places there is a feeble imitation of "going a-maying." (See Notes and Queries, 1st series, passim.)

In the Highlands of Scotland the 1st of May was celebrated as *Bel-tein* day, on which they made a fire, and performed certain puerile ceremonies, which are supposed to have had reference to the worship of *Baal*, or the sun. The Irish celebrated it by having a peculiar dish of food, the partaking of which they imagined secured them against want for the year. The Germans imagined that on the night of this day the witches had an assemblage on the Brocken in the Harz mountains. In France and Italy the youth of both sexes gathered branches in the night, which they placed before the doors of those to whom they wished to show good-will. There were many other superstitious observances connected with this day, nearly all of which are now obsolete, or about to become so.

The celebration of this day probably owed its origin to the heathen observances practised at this season of the year in honour of *Flora*, the deity who presided over fruits and flowers. (Hospinian, *De Festis Judæorum et Ethnorum*, fol. 100; Brand's *Popular Antiquities*; Strutt's *Sports and Pastimes*; Hone's *Every Day Book*.)

MAYOR. [MUNICIPAL CORPORATIONS.]

MEADOWS are properly low grounds on the banks of rivers, which, being kept moist by their situation, and also occasionally flooded by the rise of the waters, are best adapted for the growth of grass, and are generally mown for hay. Some meadows of great extent, belonging to a community or district, in which every inhabitant has a right to send his cattle to graze, under certain regulations, are never mown.

When the number of those who have a right of common pasture is not very great, they frequently agree among themselves to abstain from depasturing the meadows in spring, and, dividing them into portions, each makes hay of his share; after which the cattle are admitted in common for the remainder of the season. Thus a common meadow is converted into a *Lammis meadow*, that is, a meadow which becomes a common pasture after the 1st of August, this being the time when it is supposed that all the hay has been made and secured.

When meadows are private property they become much more valuable. The flooding is encouraged or prevented, according to circumstances, and in many cases artificial irrigation is adopted. [IRRIGATION.] If they are exposed to be too often inundated, they are protected by dams and sluices.

The herbage of low wet meadows is generally coarser and less nutritious than that of those which lie higher: hence upland hay, as it is called, is preferred for the better sort of cattle. Good grass land, to which the floods never rise, is often called meadow land when the natural herbage is permanent, and frequently made into hay.

Upland meadows are very valuable wherever there is a demand for good hay. A considerable degree of attention is required to make them most productive. Not being annually recruited by flooding, they would soon degenerate if some pains were not taken to keep up their natural fertility. This may be done in various ways: the most obvious is to recruit them frequently with the richest animal and vegetable manure, which, being spread over the surface at a time when showers are abundant, that is, either early in spring or immediately after midsummer, is washed down to the roots of the grass. A rapid growth is thus produced, which is soon perceived by comparing the

appearance of a meadow which has been manured with that of one left in its natural state. It has been asserted by many agricultural authors that the produce of hay is greater when the meadows are mown every year, provided they be occasionally manured, than when mown and depastured alternately. But the productiveness of a meadow depends entirely on the circumstances of soil and situation. A meadow, the soil of which is naturally of a rich nature, and adapted to produce fine grasses, may be mown year after year without any perceptible change in the quality of the hay; while another of inferior quality requires to be occasionally cropped close, to check the growth of the coarser grasses, and to allow the finer to rise. As to the effect of taking off the hay by mowing it, compared with that of the bite of cattle, there is little difference, except that in pasturing the grass is repeatedly cropped close to the ground as soon as it rises to such a height that the teeth of the cattle can sever it. It consequently spreads by the roots, and the pile becomes closer. The urine of the cattle greatly promotes luxuriant vegetation in rainy weather, but in hot dry weather it does more harm than good. The dung, when dropped on the grass, is of little or no value compared with what it would be if mixed up with straw, earth, or peat, or diffused through water in a tank. It is therefore an excellent practice to employ women and children to collect the fresh dung in the pastures, and to carry it to a heap of earth where it may be covered up, or to a tank where it may be diluted with water.

Of late years the practice of *soiling* has been extensively adopted; that is, all the grass is mown and carried every day, in a green state, to cows or horses tied up in a stable. By this means all the advantage of mowing for hay is obtained, besides an abundant supply of rich manure, which can be applied to the land in a liquid and diluted state, when its effect is powerful and certain. So much more fodder is produced from the land by the system of soiling, that arable fields are converted into artificial and temporary meadows, in which the different species of grasses are sown, in order to be cut green or made into hay; and when, from the nature of the soil, the herbage degenerates, the field being ploughed up again is greatly improved by this change of cultivation. [GRASS-LAND.]

When a natural meadow has been neglected, and the grass is of an inferior quality, and mixed with rank weeds and moss, it requires much care to restore it to its original fertility. In most cases the shortest method and the best is to plough it up, clean and manure it during a course of tillage, without taking very exhausting crops from it, and then to lay it down again in a clean and enriched state, by sowing the best sort of grass seeds; or, which is preferable, by inoculating, or planting in it small tufts of grass from some rich meadow, which will soon increase, and produce a new and improved sward. But where the soil is a very stiff clay, with only a small depth of good mould over it, there is some danger in breaking the old sward, for it will take a long time and much manure to reproduce a proper covering of grass. In this case it is a preferable practice to scarify the meadow, by means of instruments which do not go deep, but only tear up the surface. If this is done early in spring, when the ground is moist, and the whole surface is brought to resemble a fallow field, good grass seeds may be immediately sown. If rich manure, mixed with lime or chalk, be then spread over the land, and the whole well harrowed and rolled, the old and young grass will spring up together, and show a wonderful improvement in a very few months. It is prudent to mow this renovated meadow before the seeds of the grasses are formed, contrary to a common notion that in a thin meadow the seed should be allowed to shed, in order to increase the number of plants. The notion is good, but it should be done by sowing seed produced on other ground: for the ripening of the seed tends to exhaust the soil. If the grass be cut before the flower is faded, the roots will soon spread, and produce a new and improved sward.

It must be observed that it is not indifferent what cattle are turned into the meadow after hay-making. Horses invariably produce coarse weeds by their dung and urine; cows may be depastured in autumn, as long as the surface is dry; but sheep are far more advantageous, and may be kept in the meadows at all times, if they are not too wet for the health of the sheep, and if there is no danger of their having the rot.

MEAN. By the mean of two or more quantities is meant an intermediate quantity determined by mathematical rules. There are more ways than one of finding a mean, but the two principal results of this kind are called the *arithmetical* and the *geometrical* means. The names are not properly expressive of the distinction between them, but they are established by use.

An arithmetical mean is the simple AVERAGE, formed by adding the quantities together, and dividing by the number of quantities. A geometrical mean is the square root of the product of the quantities. Generally, let there be a number of quantities, $x_1, x_2, x_3, \&c.$, and let $\phi(x_1, x_2, x_3, \&c.)$ be a function of them which is symmetrical, that is, which is not altered when any two of them are interchanged; then if y be found from the equation

$$\phi(y, y, y, \&c.) = \phi(x_1, x_2, x_3, \&c.),$$

y may be called a species of mean.

The arithmetical mean, or average (which is always to be understood when the word mean is mentioned, unless the contrary be specified), is

taken to be the most probable result of a number of discordant quantities, which would have been the same but for errors of observation or experiment. Thus if three measures of the same length give 122, 123, and 123.4, the mean of which is 122.8, it is presumed that 122.8 is more likely to be the real length which was attempted to be measured than any other. We confine ourselves in the present article to pointing out how it may be ascertained what degree of probability belongs to such results.

In assuming the average as the most probable result, it is presumed that any one measurement is as likely to err one way as the other; that is, as likely to be too small as too great. If nothing but results be known, this presumption is justifiable; but if it be known that there is more tendency to error of one sort than the other, the most probable result cannot be ascertained until it is found out by how much the average of a very large number of observations would be affected by this tendency. Say it is known that in the long run the average will be increased .3 above the truth by a greater tendency to measure too much than too little; then $122.8 - .3$, or 122.5, is the most probable result of the preceding three observations.

It is obvious that when observations nearly agree with each other, the average must be nearly the truth required, and the nearer the agreement of the observations, the more nearly. If the observations do not agree well, the average is still more likely than anything else, but not so likely as before.

We now show how, having a number of observations, to determine the probability that the truth lies within a given degree of nearness to the average. A table must be used, which we here give to a greater extent than we should otherwise do, on account of succeeding articles. Let m be the average of a number of observations, and let $m + m$ and $m - m$ be the limits of which it is required to know what is the chance of the truth being between them. Take the difference between m and each of the results of observation, and add the squares of these differences. Multiply 100 times the number of observations by m , and divide by the square root of twice the sum just found: take the number nearest to the result in the column marked A, and opposite to it, in the column marked B, will be found the number of chances out of 10,000 for the degree of nearness required.

35	3794	70	6778	105	8624						

Suppose, for example, that seven observations give 10.03, 10.71, 10.98, 10.26, 10.30, 10.72, 10.81, the average of which is 10.54, differing from the respective observations by .51, .17, .44, .28, .24, .18, and .27, the sum of the squares of which is .7239, twice which is 1.4478, the square root of which is 1.203. Let it be required to find the chance of the truth lying between $10.54 + .06$ and $10.54 - .06$, we have then to multiply 700 by .06, which gives 42, and to divide by 1.203, which gives 34.9. Opposite to 35 in the column A is found 3794, so that 3794 out of 10,000, or 37.94 to 6206 is the chance of the result lying between the limits given: that is, nearly 31 to 19 against it. If the limits proposed had been $10.54 + .1$ and $10.54 - .1$, 700 multiplied by .1 and divided by 1.203 would have given 58.2. Opposite to 58 in the table we find 5879, so that it is 5879 to 4121, or about 59 to 41, in favour of the result lying between 10.64 and 10.44.

In the preceding rule it is supposed that all the observations are

equally trustworthy, or that there is no circumstance which would beforehand lead us to suppose that any one is more likely to be true than another. If this be not the case, no rule can be applied except one which depends on the observer's judgment. He must make the different observations reckon as different numbers of observations, allowing any one observation to count as more than one, if he believes it to be better than the rest. Thus, suppose three observations to give 26, 28, and 29, and that it is thought there is reason to prefer 28 to the others, and 29 to 26, so that 28 ranks in the observer's mind as being as good as a mean of eight observations, 29 of six, and 26 of four. It must then be considered that there have been $8 + 6 + 4$, or 18 observations, of which 8 have given 28, 6 have given 29, and 4 have given 26. These numbers, 8, 6, and 4, are called the *weights* of the several observations 28, 29, and 26, and the alteration in the preceding rule is as follows:—In forming the average, multiply each observation by its weight; add the result, and divide by the sum of the weights. Thus $8 \times 28 + 6 \times 29 + 4 \times 26 = 502$, which divided by $8 + 6 + 4$, or 18, is 27.89, the most probable result. In finding the probability of the truth lying within given limits on one side or the other of this most probable average, let the average be M as before, and the limits $M + m$ and $M - m$; take the difference between M and each of the results of observation, multiply the square of each difference by the weight of its observation, and add the results. Multiply 100 times the sum of the weights by m , and divide by the square root of twice the sum just found; take the number nearest to the result in the column marked A, and opposite to it in the column marked B will be found the number of chances out of 10,000 for the degree of nearness required. Thus if in the preceding instance we ask what is the chance of the truth lying between $27.89 + .2$ and $27.89 - .2$, we observe that 27.89 differs from the several results by 1.89, .11, and 1.11, the squares of which multiplied by 4, 8, and 6, and the results added together, give 21.7778, twice which is 43.5556, the square root of which is 6.600. And 100 times the sum of the weights, or 1800, multiplied by .2, is 360, which divided by 6.6 gives 54.6. Opposite to 55 in column A we find 5633 in column B; that is, we have 5633 to 4367, or about 56 to 44 in favour of the truth lying between the limits specified.

The inverse problem is as follows: given the observations, required the limits of difference from the average between which it is a given chance, a to b , that the truth shall lie. In both cases the first process is to turn $a : (a + b)$ into a decimal fraction of four places, and to take the numerator of such fraction.

Look for the numerator in column B, find the number nearest to it, and take out the number corresponding in column A. Multiply this by the square root used in the direct rule, and divide by 100 times the number of observations, or, if they are not equally good, by 100 times the sum of the weights. The quotient is the answer required. But when, as most frequently happens, an even chance is the given chance, use 47.7 instead of the number found in column A.

In the first of the given instances it is required to know within what limits it is 99 to 1 that the truth is contained. Here $99 : (99 + 1)$ is .9900, and looking for 9900 in column B we find 9899 opposite to 182 in column A. Multiply 182 by 1.203, which gives 218.946, which divided by 700 gives .313, so that it is 99 to 1 that the truth lies between $10.54 + .313$ and $10.54 - .313$.

In the second instance, required the limits within which it is an even chance that the truth is contained. Multiply 47.7 by 6.6, and divide by 1800, which gives .175; and it is an even chance that the truth lies between $27.89 + .175$ and $27.89 - .175$.

The amount of departure from the average within which, on one side or the other, it is an even chance that the truth shall lie, is called the *probable error* of the observation or average of observations to which it refers. When the probable error of any one observation is given, that of the average is found by dividing it by the square root of the number of observations. Thus, if there be 100 observations, of each of which it is an even chance that it is within .1 of the truth; then the square root of 100 being 10, and $.1 \div 10$ being .01, it is an even chance that the average of the hundred observations is within .01 of the truth.

For further account of the matters contained in this article, see *PROBABILITIES, THEORY OF; OBSERVATION; RISK*. For description of methods without demonstration, see Lardner's *Cabinet Cyclopædia*, Essay on Probabilities, or Poisson on Probabilities. The tables may be found to greater extent in the first article cited, and also in the Berlin *Astronomisches Jahrbuch* for 1834.

MEASLES (*Morbilli*, *Rubeola*) is the popular name of a contagious disease, characterised by an eruption on the skin, and affecting chiefly children.

The etymology of the word measles is uncertain, but its application to the disease we are treating of was probably borrowed from an appearance so denominated in pork, to which the eruption bears resemblance. Measles is ushered in by more or less fever, a running from the nostrils and eyes, with some inflammation of the latter, sneezing, hoarseness, a dry cough, difficulty of respiration, and occasionally slight soreness of the throat. From four to six days after the commencement of these symptoms a rash begins to appear, which first shows itself in distinct, red, and nearly circular spots, having some resemblance to flea-bites: these spots gradually coalesce and form small slightly elevated patches of an irregular figure, but approaching nearest to that of semicircles or crescents. The patches first show themselves on the forehead and

face, and gradually extend downwards to the trunk and extremities. At the commencement of the eruption the catarrhal symptoms and fever are somewhat augmented, and during its height the whole face is often swollen and the eyelids thereby closed; on its decline, which begins on the fourth or fifth day, the fever ceases, and from those parts of the body previously covered by eruption the cuticle separates in small bran-like scales. A diarrhoea now commonly supervenes, and affords relief to the other symptoms. This, however, is the period when the danger, which is a consequence rather than a concomitant of measles, commences. The cough, which has continued throughout the active period of the disease, now assumes a more serious character; the expectoration, which hitherto has been simply mucus, indicative of the inflammation being confined to the mucous membrane of the bronchial tubes, becomes bloody, or mixed with pus, showing either that inflammation has attacked the proper substance of the lungs, or that tuberculous deposits have taken place in these organs, constituting pulmonary consumption. If the patient happily escape these dangers, others, less fatal indeed, but scarcely less to be dreaded, not unfrequently show themselves, among the most severe of which are obstinate ophthalmia and inflammation of the internal parts of the ear, the former not unfrequently terminating in partial or total loss of vision, and the latter in deafness. It must be confessed, however, that this is a picture rather of what may and occasionally does happen than of what takes place in the majority of instances; such severe terminations of the disorder are confined chiefly to the ill-fed and ill-clad children of the poor, and to the more sickly ones of the opulent.

Measles frequently occurs as an epidemic, in this country usually at the beginning of spring. These epidemics vary considerably in character, being sometimes benign, at other times very fatal, and occasionally they are observed to prevail in conjunction with small-pox; like the latter disease, measles rarely attacks the same individual twice. Experiments have been made to determine how far inoculation with the blood of the parts on which the eruption appeared might succeed in moderating the violence of the disease thus artificially produced; but the cases in which it was tried were not sufficiently satisfactory to warrant its general adoption. Measles, before the outbreak of the rash, may be mistaken for severe catarrh; the eruption itself is liable to be confounded with that of roseola, scarlatina, strophulus, lichen, urticaria, incipient small-pox, &c.; but the crescentic shape of the patches and the catarrhal character of the other symptoms can hardly fail to remove any doubt as to the nature of the disease.

With respect to the treatment, little is required during the eruptive stage of the disorder, which is seldom attended with danger. It is chiefly necessary to open the bowels, to confine the patient to a light vegetable diet, with cold acidulated aqueous drinks, and to maintain a cool temperature in the room, which should be moderately darkened. Where the skin is dry and hot, sponging it with cold water has been recommended and practised with benefit. The old practice of confining the patient in heated chambers, and covered with an overwhelming quantity of bed-clothes, is now justly abandoned: the free use of the lancet during the eruptive period of the disease is likewise laid aside, and its employment restricted to those cases in which any of the vital or important organs are threatened or attacked by inflammation. Cases in which the vital powers are low, to which the name *rubeola putrida* has been applied, of course will require an opposite mode of treatment, as the exhibition of bark, the mineral acids, and wine, together with a nutritious diet and a pure atmosphere: these, too, are the remedies which prove most serviceable in checking the diarrhoea, if injuriously protracted.

MEASURE. One number or magnitude is said to measure another, when the first is contained an exact number of times in the second. [INCOMMENSURABLE; PROPORTION.]

MEASURES. [STANDARDS; WEIGHTS AND MEASURES.]

MECHANICAL POWERS is the name given to certain *simple machines* or *engines*, for these words are applied indifferently, either of which is occasionally used by itself in moving bodies or raising weights, or any of which are combined together in the formation of the complex constructions which are employed in manufactures and the arts. Frequently however, in investigations relating to statical equilibrium, the properties of the mechanical powers are introduced when no machine is contemplated; as when, at some part of a plane surface, the effect of a pressure at another part is determined by the ratio of the distances from a supposed point of support.

The several machines to which the name of mechanical powers is applied are the **LEVER**, the **WHEEL AND AXLE**, the **INCLINED PLANE**, the **WEDGE**, the **SCREW**, and the **FUNICULAR MACHINE**.

The object proposed in every machine is to transmit a force from the point at which it is immediately applied to that at which some resistance is to be overcome or some operation to be performed; and, in the transmission, the intensity of the motive power is to be increased so that effects may be produced which could not be accomplished by that power alone. The increase of the power is obtained by causing part of the resistance which is to be overcome to rest on the machine or on the fixed points which serve for its support, so that only the part which remains is opposed to the motive force. Thus, if it be required to raise a heavy body to a certain height from the ground, no exertion of human or animal strength may be sufficient, if directly applied, to accomplish the end; but if a plane inclined to the horizon and extend-

ing from the object to the spot to which the latter is to be raised be formed, and the object can be placed on its foot, the force of gravity in the vertical direction being resolved into two forces, one of which is destroyed by the reaction of the plane, the other may be overcome by a motive power less in intensity than that which would be required if a direct application of force were made; in fact, the force which will suffice for the attainment of the end diminishes in proportion as the length of the plane is greater.

The manner of overcoming a resistance, which is specified in this example, will serve also to illustrate the well known fact that in every application of a mechanical contrivance to overcome a resistance, as much advantage is lost in respect of time or space as is gained in respect of power. For it is evident that, in order to raise the object vertically through a space equal to the height of the plane, it would be necessary to move it over a space equal to the length of the plane; that is, through a space which bears the same ratio to the vertical height as the weight of the object bears to the power required to move it up the plane.

An account of the applications of the mechanical powers in the construction of complex machines would involve descriptions of most of the engines by which human labour is abridged or dispensed with; some of the most typical of these are referred to under MACHINE, where the reader will also find a reference to works of authority on the subject.

In determining the efficacy of the mechanical powers it is evidently necessary to consider their parts as mathematical lines, to assume that the axles are without friction and cords without rigidity, so that a perfect equilibrium may subsist in the machine itself before the moving power is applied. The most simple lever, for example, of a physical kind, is a rod of wood or a bar of iron, the arms of which, on opposite sides of the fulcrum, are of unequal weights; and, in order to reduce such a lever to a state from which the exact relation between the opposing powers may be found, the weight of each arm must be computed, and being, in imagination, applied at the centre of gravity of the arm, the product of the weight multiplied by the distance of the centre of gravity from the fulcrum is to be added to the momentum of the weight actually applied to the same arm of the lever. The sums of these momenta, when the actual machine is in equilibrio, serve to determine the correct relation between the opposing powers. The conditions of equilibrium being determined, any excess of the motive power above that which enters into those conditions will evidently overcome the resistance, or produce motion in the machine.

MECHANICS is the science in which are investigated the actions of bodies on one another, either directly or by means of machinery.

These actions may be simple pressures without motion, as when one body being supported in any manner, another is placed upon it, either vertically or in some oblique position; or they may be such as are accompanied by motion, and these may arise either from the mutual attractions which all bodies in nature exercise upon each other, or from the collisions of bodies in motion with others which may be previously in motion or at rest.

The term is particularly applied to the mutual actions of solid bodies: the actions of fluids on solids form, in part, the subjects of HYDROSTATICS and HYDRODYNAMICS; but these, as well as *pneumatics*, are now frequently included under the general name *mechanics*. When bodies are at rest, and the actions are such as to maintain them in that state, the laws of the actions constitute that branch which is called STATICS; but when motion is concerned, the laws and phenomena constitute what is called DYNAMICS.

In all the branches of general mechanics the investigations are founded on experiment and are conducted by geometrical or algebraical processes: hence the science forms one of the departments of experimental philosophy, and also of mixed mathematics. This last denomination is applied to mechanics because in the latter are involved several qualities of bodies which do not enter into the researches of pure science, such as *mass* or *quantity of material*, *inertia*, *hardness*, *elasticity*, *time*, *space*, and *power* or *force*. The last-mentioned term is used to express the cause of the actions of bodies on one another; but we have no other conception of it than that it is productive of motion or of a tendency to motion, or that it arrests an actual motion or renders a tendency to motion ineffectual. When opposing forces act on a body so as to destroy each other's effects and keep the body unmoved, that body is said to be in a state of *equilibrium*; and this state is distinguished from that of mere rest, since the latter implies the absence of any cause by which the body might change its place.

The invention of simple machines for moving masses of any material which it might be beyond the unaided power of man to transport to a distance, must have taken place in the earliest ages of the world. Human ingenuity would readily suggest the application of a rod or bar of wood or iron, for the purpose of lifting a heavy body from the ground; and very little experience would suffice to show that rolling or pushing a block of stone up sloping ground was a much easier operation than that of raising it vertically by the strength of men's arms. Thus may have arisen the employment of the *lever* and *inclined plane*; and from these, subsequently, the *wheel and axle*, the *pulley*, the *wedge*, and the *screw*, were derived. The simple means here indicated would be sufficient, with the aid of manual labour, to build up the most massive cyclopean edifice; and even the vast materials which form the

roofs of the Egyptian temples may have been raised to their places by means of inclined planes, formed of earth for the purpose, on the exterior of the walls, and afterwards removed.

The steps by which the art of constructing machines advanced have not been distinctly recorded; and the work of Vitruvius on architecture is almost the only source whence can be obtained an account of such as were in use in and before the time of that engineer (the age of Augustus or Vespasian). From the descriptions there given, it appears that among the mechanical powers then in use were the lever, the windlass, and the assemblage of pulleys. Vitruvius also mentions some ingenious contrivances for transporting heavy blocks of stone from the quarries, and a *forcing-pump*, the invention of which he ascribes to Ctesibius, for supplying the public fountains. He describes a complex machinery, consisting of *wheels* driving each other by *cogs* or *teeth*, which was applied to carriages or ships for the purpose of measuring the distances travelled or sailed; and he enters fully into the construction of *engines* for throwing darts or masses of stone. The *muscular strength* of men was then employed as a moving power in turning mills: *wheels* impelled by *river currents* acting on float-boards (*pennæ*) gave motion to machinery for grinding corn; and *wheels* turned by *men* walking on them were used for raising water by buckets or otherwise. Vitruvius generally mentions the names given by the Greeks to the machinery; and it might, without great risk of error, be presumed that much of that which he describes was in use among the latter people at, or even before, the time when the Parthenon was raised. There are no distinct intimations of the existence of *windmills* till the 12th century. The expansive force of *steam* can only be said to have become a moving power at the end of the 17th century, and then it was employed merely to raise water. Its general application to machinery must be dated from the year 1768.

In tracing the progress of discovery concerning the mathematical theory of mechanical action, we shall have little to notice till we come to the 16th century; for the ancients, who devoted themselves with so much ardour to the researches of pure science, almost entirely neglected the application of the latter to subjects which appeared to them to terminate in mere practical utility. It must be observed however that Aristotle, who left no department of nature untouched, has noticed, in his mechanical questions, the equilibrium of unequal weights on the unequal arms of a balanced lever, though he gives a very unphilosophical reason for the fact. But in his 'Physics' he states correctly that if two forces move with velocities reciprocally proportional to their intensities, they will exert equal efforts: this may apply to a well-known property of the lever, but it may have been meant to refer only to the effect of two unequal bodies moving with unequal velocities, and striking each other or a third body.

Sicily enjoys the honour of having given birth to the first philosopher who can properly be said to have been a theoretical mechanician: we allude to Archimedes, who died about 212 B.C., and in whose works there is direct evidence of an effort to determine the principle of equilibrium in machines. Commencing, in the treatise whose Latin title is 'De Æquiponderantibus,' with the axiom that two equal weights balance each other on a lever (of uniform dimensions), when at equal distances from the fulcrum, he supposes the weights to be divided into an equal number of equal parts, and that the parts are removed to equal distances from the point of support; observing then that the equilibrium still subsists, he proceeds, by the method of exhaustions, to show that it always will take place provided the bodies are inversely proportional to their distances from the fulcrum. Archimedes thence concludes that there must exist in every one body, considered as an assemblage of smaller bodies, a centre of force (that is, a centre of gravity) corresponding to the fulcrum in the former case; and he proceeds, by the analysis of that day, to investigate the seat of the centre of force in a triangle, a parabola, and a paraboloid.

This philosopher has obtained celebrity by the contrivances which he is said to have adopted for the defence of Syracuse. No precise account is given of the machinery which he employed to raise up and destroy the galleys of the enemy, and the effects are probably exaggerated. The vessels must have been close to the walls, and it is conceivable that, by hooks at the ends of chains which were suspended from levers on the ramparts, the rigging, or some parts of the turrets erected as usual on the decks, in order to enable the assailants to pass over the parapets, might be caught; then, the levers being raised by the force of men or otherwise, the vessels or the turrets would be easily overturned.

During about 1800 years, which elapsed between the time of Archimedes and that of Cardan, we have no other notices concerning the theory of mechanics (beyond those which occur in the writings of the former mathematician), than such as are contained in the 'Mathematical Collections' of Pappus, which amount merely to a statement that the ancients had reduced the theory of every machine to that of the lever, and an unsuccessful attempt to explain the cause of the equilibrium of a body on an inclined plane. It is remarkable moreover that both Cardan and, subsequently, the Marquis Ubaldi (the latter of whom published, in 1577, a treatise in which he explains at length the combinations of pulleys, and reduces their theory to that of the lever) should also have given erroneous solutions of the problem concerning that equilibrium. The discovery of the true theory of the inclined plane was however, about the same time, made by Stevinus, a native

of Flanders. This mathematician and engineer supposed a chain of uniform dimensions to be placed on a doubly inclined plane, having a common summit and base, the chain being perfectly free to slide on the planes, and its ends hanging vertically to equal distances below the base; then, in order to prove that the chain would remain at rest, he shows that if any motion should take place, it might continue for ever; and this he concludes to be absurd. As the argument holds good when one of the two planes is in a vertical position, Stevinus infers that, when a body is in equilibrium upon a plane, the retaining power is to the weight as the height of the plane is to its length; and he further shows that if three forces act on any point, they hold the latter in equilibrium when they are proportional to the three sides of a triangle formed by lines drawn parallel to the directions of the forces. It should be remarked however that Stevinus demonstrates the law in that case only in which two of the forces are at right angles to each other. He died in 1635.

To Galileo we are indebted for the first reduction of mechanical propositions to purely mathematical formulæ. In order to demonstrate the equilibrium of a body on an inclined plane, he imagined the weight and the sustaining power to be applied to the ends of a bent lever whose arms were of equal length and perpendicular to the vertical and slant sides of the plane; then reducing the lever to a straight one, between the lines of direction of the weight and power, it was easy to prove that the forces in equilibrium on the plane were also in equilibrium on the lever, and were to one another as the length to the height of the plane.

But the most important discoveries of Galileo were those which relate to the times of descent, the spaces descended, and the velocities acquired when bodies fall by the action of gravity. He made observations on the motions of *pendulums*, and determined that the times of their vibrations are proportioned to the square roots of their lengths; he also gave theorems for the composition of two motions, when both are uniform, when both are accelerated, and when one is uniform and the other accelerated. Nor should we omit to state that he was the first to obtain expressions for the strength of materials in resisting the strains to which they are subject. It deserves notice moreover that Galileo, in opposing the arguments of one of his contemporaries concerning the law of the descent of bodies by gravity, makes a supposition that the spaces descended with the accelerated motion may be divided into equal parts, each so small that the motion during the time of describing it may, without sensible error, be considered as uniform; an hypothesis corresponding exactly to that which, agreeably to the principles of the modern analysis, is now employed in investigations concerning variable motions.

The theory of the *motions of fluids* was, apparently, first cultivated in Italy by Castelli, who wrote on the subject in 1638; and about the same time Torricelli, having discovered the existence of a space void of air in the upper part of a tube filled with mercury, its open end being immersed in a vessel of that fluid, was enabled to refute the ancient notion that nature *abhorred* a vacuum. The latter was subsequently led to the conclusion that the pressure of the atmosphere is the cause of the support of a column of mercury in a tube, and also of the ascent of water in pumps. Both of these writers were pupils of Galileo; and, soon after the time of this philosopher, the French mathematicians Descartes, Pascal, Fermat, and Roberval, prosecuted with ardour the *new science*, as that of mechanics was called. Among the fruits of their researches may be named the determination of the centres of oscillation and percussion in a body or system of bodies vibrating about a fixed axis. The impulse given by Galileo, being thus continued by a succession of men of talent both in Italy and France, caused the science to advance with an accelerated movement, and soon put it in a condition to embrace all the subjects of terrestrial physics.

The mechanics of that age was not however entirely emancipated from the trammels of a false philosophy; and the theory of Descartes, concerning the communication of motion when bodies strike each other, is remarkable on account of the metaphysical principle which it involves. In speaking of the *collision of bodies*, he gives as a reason why the same momentum should exist after as before the impact, that it depends on the divine immutability. God having created a certain quantity of motion to serve as the cause of all the operations of nature, that quantity, he conceives, can never be increased or diminished. Yet there is some reason to think that Descartes had better notions concerning the phenomena of collision, for he states correctly, in one of his letters, that the motion of a body when it strikes another which is at rest becomes divided between the two masses, and that the resulting velocity is diminished as the mass is augmented. The chief feature in the physics of Descartes is his supposition that the planets revolve about the sun in vortices of æther, the particles of which, having acquired a certain degree of centrifugal force, act on the planets and prevent them from falling together in the centre of the system. He supposed that the like vortices surround each planet: but the particles of æther, having less specific gravity than the bodies on the surface of the planet, the tendency of these bodies to that surface prevails over the force by which the æther causes them to recede from thence.

The laws of the collision of bodies, which had been in vain attempted by Descartes, were at length, and nearly at the same time, discovered

by the English mathematicians Wallis and Sir Christopher Wren, and by Huyghens on the Continent. The first of these, in his treatise '*De Motu*' (1670), divides bodies into such as are hard and such as are elastic, and he explains the phenomena attending the shock of bodies of both kinds. In that of hard bodies he adopts as an hypothesis that the body struck destroys as much motion in the striking body as the latter communicates to it; and in elastic bodies he considers the forces of compression and restitution to be proportional, in each, to the velocities before the shock. The name of Huyghens has become celebrated from the discovery of the properties of *cycloidal curves*, and the attempt to make the lower extremity of a clock-pendulum vibrate in an arc of that kind, in order that the times of vibration might be equal, whatever were the extent of the arc described. This attempt did not succeed; but, being led in the course of his inquiries to investigate the position of the centre of oscillation in a compound pendulum, Huyghens found that when several pendulous bodies descend by gravity and afterwards re-ascend by the acquired velocities, in whatever way they may act upon each other, their common centre of gravity cannot rise higher than the point from whence it descended. This proposition is considered as proved from the fact that, if it were otherwise, the centre of gravity might by mechanical means be made to rise continually higher, and thus perpetual motion might ensue: but this is impossible.

In 1687 Newton's great work concerning the mathematical principles of natural philosophy was first published, and from that time the mechanical sciences, which had hitherto been confined to the action of bodies on each other at the surface of the earth, were made to comprehend the laws of planetary motion. The '*Principia*,' as the work is called, commences with the three well known axioms in philosophy, or *laws of motion*. Assuming then as an hypothesis, that all the bodies of the universe and all the particles of every body exert on each other mutual attractions; assuming also that the planetary bodies were originally put in motion by impulsive forces; the rotations of these bodies on their axes, their revolutions in their orbits, and all the perturbations by which their movements are varied, are explained by means of the elementary theorem for the composition and resolution of motions. The *oscillations of pendulums*, the *theory of projectiles*, the *movements of fluids*, and the *resistance* opposed by the latter to the motions of bodies immersed in them, are also in the same work investigated at length.

Contemporary with Wallis, Wren, and Newton in England, were, on the Continent, the celebrated Leibnitz and the two elder Bernoullis, all of whom contributed greatly to the advancement of mechanical science by their investigations concerning the laws of motion in terrestrial bodies; and to the rivalry as well as the talents of these great men we owe some of the most important discoveries in that branch of learning. At this time the *fluxional* or *differential calculus* was discovered, and had acquired an algorithm; and they who adopted its principles appear to have been anxious to show its superiority over the ancient geometrical analysis, by proposing to their opponents problems which could scarcely be solved by the latter method. With some such views Leibnitz proposed the determination of that curve along which a body descending would describe equal vertical spaces in equal times; James Bernoulli proposed to find the figure assumed by a flexible cord or chain when suspended at the extremities [*CATENARY*]; and John Bernoulli, to find the curve of swiftest descent. [*CYCLOID*.] Numerous other problems of the like nature were given out among the parties, and the solutions could not fail, if no other benefit arose, of carrying the new calculus to a considerable degree of perfection.

From the time of Newton mechanical science was, till lately, but little cultivated in this country; but on the Continent a succession of illustrious men continued to prosecute the investigation of subjects connected with it, and by the employment of analytical processes they rendered comparatively easy the application of its principles to the researches of *physical astronomy*.

The mathematicians who may be considered as the immediate successors of Newton were chiefly Euler, D'Alembert, and Clairaut; and in the works of the first of these are investigated all the circumstances attending the phenomena of *rectilinear* and *curvilinear motion* when a body in vacuo or in a resisting medium is subject to any forces whatever. But the most remarkable event in the history of the sciences, after the discoveries of the English philosopher, was the solution of the celebrated *problem of the three bodies*: or that whose object is to determine the motions of a body when attracted by and revolving about another, and continually disturbed by the attraction of a third. This was, at the same time (about 1752), and independently of each other, accomplished by the three learned men above named, and it now constitutes the basis of the whole planetary theory. The '*Mécanique Analytique*' of La Grange, which was published in 1788, and the '*Mécanique Céleste*' of La Place (1798 to 1825), contain the last accessions which the mechanical sciences have since received; and these sciences now comprehend the *laws of force* or *motion*, from the properties of the simple lever to the phenomena of the heavenly bodies.

It may have been seen above that the first general principle in mechanics is that of the *equilibrium of bodies* on a lever; and a knowledge of it may be ascribed to Archimedes. The extension of the

principle to all the mechanical powers was long an unsolved problem, and the solution may be said to have been first made known to the world by the discovery of Stevinus, relating to the sustaining power on an inclined plane. A second general principle may be conceived to be that of the *composition of motions or forces*; and its discovery is to be ascribed to Galileo. Daniel Bernoulli (about 1726) was the first to demonstrate the rule of the *composition of forces* independently of motion; but the application of the principle as a means of obtaining general equations of equilibrium seems to have been first made in the 'Projet d'une Nouvelle Mécanique,' which was published by Varignon in 1687.

La Grange treats as a third principle in mechanics that of *virtual velocities*. By this is meant those which bodies in equilibrio would have at the first instant of their motion, in the event of the equilibrio being disturbed. Indications of this principle are found in the writings of Galileo, Wallis, and Descartes, but John Bernoulli is thought to have been the first who showed its utility in resolving statical problems. [VIRTUAL VELOCITIES.] A general method of solving mechanical propositions was discovered by D'Alembert, and it may be thus enunciated. If there be impressed on bodies motions which they are forced to change in consequence of their mutual actions, those motions may be considered as compounded of the motions which the bodies do really take, and of those which are destroyed. Whence it results that these last must be such that if they alone existed the bodies would be in equilibrio. In order to avoid the decompositions of motions which this principle requires, an equation is frequently made between the general analytical expression for a force and the expression for those forces which produce the observed motions. [FORCES, IMPRESSED.] The manner of estimating the value of a mechanical force is various; and a difference in the expression of the value gave rise to disputes which continued during nearly all the first half of the 18th century. [FORCE.]

Besides the principles above mentioned there occur in mechanical investigations several others, which it will be proper to state briefly in this place.

That which is called the *preservation of living forces* is a consequence of the discovery of Huyghens concerning the movement of the centre of gravity in a compound body. For the space described by that centre is expressed by the quotient arising from the sum of the products of the mass of each body into the distance it passes over, divided by the sum of the masses; and since the spaces descended by bodies when acted on by gravity are proportional to the squares of the velocities, it follows that the sum of the products of the mass of each body into the square of its velocity is constant, whether the bodies move jointly in any manner, or whether they descend freely through equal vertical spaces.

The *preservation of the centre of gravity* is a principle which contains the discovery of Newton, that the motion of the common centre of gravity of several bodies is not affected by the mutual attractions of the bodies. It was subsequently extended by D'Alembert, who shows that if the bodies are solicited by a constant accelerative force in directions either parallel to each other or tending to a fixed point, the centre of gravity must describe the same line as if the bodies were free.

The *preservation of areas* seems to have been discovered simultaneously by Euler, Daniel Bernoulli, and the Chevalier D'Arci, about 1750. According to the latter it is an extension of Newton's theorem that the *radii vectores* of revolving bodies describe equal areas in equal times, and it consists in this: that the sum of the products of the masses of revolving bodies into the areas described by their *radii vectores* about a fixed point is proportional to the time. Or the sum of the products of the masses into the velocities and into the perpendiculars let fall from the fixed point on the lines of direction of the motions is constant.

The *principle of least action* originally signified, that when bodies act on each other, the sum of the products of the masses into the velocities and spaces described is a minimum. But considered in the most general sense, agreeably to the extension given to it by La Grange, the principle consists in this: that in trajectories described by bodies subject to central forces, the integral of the velocity multiplied by the element of the orbit is always a maximum or a minimum.

A general outline of that part of mechanics which relates to the equilibrium of solid bodies is given under the word STATICS; and the details of the subjects may be seen under LEVER, WHEELS, &c. The part of mechanics which relates to bodies in motion appears under the words referred to in the article DYNAMICS.

MECHLOIC ACID. This acid was formed in 1835 by Couerbe, by passing chlorine gas over fused meconin. When purified by solution in potash, and precipitation by nitric acid, it exists in the state of colourless prismatic crystals, soluble in cold water, but more so in hot: alcohol and ether dissolve it sparingly. It melts at about 257°; at 376° it is volatilised; and by a strong heat it is decomposed. It contains

Hydrogen	4.07
Carbon	48.72
Oxygen	47.21

100.00

MECONAMIC ACID. [MECONIC ACID.]

MECONATES. [MECONIC ACID.]

MECONIC ACID ($C_{14}H_{11}O_8, 3HO$). A substance found in opium, in which it exists in combination with the alkali morphia. It was first noticed by Seguin in 1804, and a few years after, more particularly described by Sertuerner, who named it *mecon* ($\mu\eta\kappa\omega\nu$), poppy. Meconate of lime is one of the results of a peculiar process for obtaining morphia from opium [OPIUM, ALKALOIDS OF]; this is put into ten times its weight of water at 200°, and hydrochloric acid is added until it is dissolved; the solution is to be filtered, and on cooling it deposits bi-meconate of lime in the state of light, scaly, or acicular crystals; these are again to be dissolved in hot and very dilute hydrochloric acid, which separates the remainder of the lime, and on cooling, the meconic acid crystallises in scales containing six equivalents of water of crystallisation. They are to be freed from colouring matter by subsequent treatment with purified animal charcoal, and recrystallisation. Meconic acid has then the following properties: it acts on litmus paper, and has a sour taste; it is soluble in four times its weight of water, and also in alcohol. The crystals do not alter by exposure to the air, but when heated to 212° they lose 21.5 per cent. of water, and become opaque. Although when heated even to near 250° the acid is not totally decomposed, yet the boiling solution gives out carbonic acid gas, and a brown substance is formed, which is comenic acid. When strongly heated, it is totally vaporised. When mixed with a solution of chloride of gold, and heated, it is decomposed, and metallic gold is precipitated. This acid possesses the characteristic property of forming a purplish-red coloured solution with the persalts of iron, and this is regarded as one of the best tests of its presence in the opium from which it is derived. It has been asserted that meconic acid is an antidote in cases of poisoning by corrosive sublimate, but this is not the case. It has no effect whatever.

Meconic acid is tribasic; one, two, or three atoms of the water in the above formula being replaceable by an equal number of equivalents of a base with formation of mono-, bi-, or tri-metallic salts, called *meconates*. Their properties are as follow:—*Meconate of Ammonia* crystallises in quadrilateral prisms, dissolves in one and a half times its weight of water, yields water when heated, and afterwards sublimes without decomposing. *Meconate of Potash* crystallises in tables and leaves, contains water of crystallisation, and is soluble in twice its weight of cold water. *Meconate of Soda* crystallises in fine needles, which contain much water of crystallisation, and are soluble in five times their weight of water. *Meconate of Lime* forms acicular crystals, which contain water of crystallisation, and are soluble in eight times their weight of water. When the acid is in excess the salt crystallises in prisms, and is difficultly soluble in water. *Meconate of Magnesia* when neutral is only slightly soluble, but the supersalt dissolves readily; it crystallises in flattened needles, which are brilliant and transparent, and have an acid and bitter taste. *Meconate of Baryta* is slightly soluble in water. *Meconate of Iron* is a colourless and very soluble salt, which becomes red by exposure to the air, and more rapidly by the addition of nitric acid. The *Permeconate of Iron* is also a soluble salt, and is of a fine red colour, destroyed by heat, by sulphurous acid, and protoxide of tin. *Meconate of Silver* explodes when heated. *Meconate of Oxide of Ethyl*, or *Meconic Ether*, or *Ethyl-meconic acid* ($C_4H_5O, 2HO, C_{14}H_{11}O_8$), separates out in acicular crystals on evaporating the liquid formed on passing dry hydrochloric acid gas through a solution of meconic acid in absolute alcohol. It forms very stable salts, called *Ethylmeconates*. The mother-liquor from the preparation of ethylmeconic acid contains crystalline *Diethylmeconic acid* ($2C_4H_5O, HO, C_{14}H_{11}O_8$).

Meconamic acid ($C_{14}H_5NO_{12}$) is precipitated when hydrochloric acid is added to *Meconamate of Ammonia*. The latter salt is produced by the reaction of ammonia and ethylmeconic acid.

Comenic acid, *Metameconic acid*, *Parameconic acid* ($C_{12}H_2O_8, 2HO$). It has been mentioned above that when a solution of meconic acid is heated to ebullition, carbonic acid is evolved, and a brownish solution results; this consists of colouring matter and comenic acid. When a meconate, as of potash or lime, is boiled with hydrochloric acid, no colouring matter results, and yet comenic acid is formed.

This acid is soluble in sixteen times its weight of boiling water, and separates on cooling in hard anhydrous grains, which, like the meconic acid, redden the persalts of iron, but they differ from it in every other respect.

It is formed by the mere separation of carbonic acid, by subtracting two equivalents of which from meconic acid we obtain the acid in question:—

Comenic acid is bibasic, forming neutral and acid *comenates*. *Ethyl-comenic acid* is formed in a similar way to ethylmeconic acid. *Chloro-comenic acid* ($C_{12}H_3ClO_{10} + 3Aq.$) is obtained by the action of chlorine on comenic acid. It crystallises in short prisms.

Comenamic acid ($C_{12}H_5NO_9$). Prepared by the action of heat upon a solution of comenate of ammonia. On adding a little hydrochloric acid, and cooling, it crystallises out in plates. The *comenamates* are monobasic.

Pyromeconic acid ($C_{10}H_8O_6$) is obtained by heating meconic acid, which yields about one-fifth of its weight. It is purified by pressure between folds of blotting paper, and crystallisation from solution in water. It is fusible between 248° and 257° , and then flows like oil; it is entirely soluble at a moderate temperature, and is more soluble in alcohol than in water. It turns the persalts of iron red, and its salts are generally soluble in water. It is formed by the separation of four equivalents of carbonic acid and one equivalent of water, from two equivalents of meconic acid. It is colourless, very sour, and mono-basic.

Bromine and iodine displace hydrogen, and form *Bromo-* and *Iodopyromeconic acids*.

MECONIN, or *Opianyl* ($C_{20}H_{10}O_8$), a neutral principle existing in opium, first noticed by Dablane, and more particularly examined by Couerbe. To obtain it, an infusion of opium, from which the morphine has been precipitated, is to be evaporated, and the crystallised matter obtained, after being pressed, is to be treated with boiling alcohol; the solution contains narceine and colouring matter, from which it is to be separated by subsequent operations. [OPIUM, ALKALOIDS OF.]

The properties of meconin are, that it is colourless, inodorous, is at first tasteless, but afterwards acrid; it is soluble in water, alcohol, and ether, and crystallises well from any of them; the crystalline form is a six-sided prism with dihedral summits; it fuses at 194° , and is volatilised at 310° , without undergoing any change of properties. It is soluble in about 265 parts of cold water, and 20 of boiling water. Sulphuric acid gives it a fine green or purplish colour. Chlorine renders it of a blood-red colour, forming *Mechloic acid*. It does not act either as an acid or an alkali. Nitric acid converts it into *Nitro-meconin* ($C_{20}H_9(NO_3)O_8$).

MEDALLET, a small medal.

MEDALLION, a medal of an extraordinary size. Medallions were never used as current coin; the term is more particularly applied to ancient Roman medals.

MEDALLION, in architecture, any circular or oval tablet on which heads, animals, flowers, or other objects, are represented in relief.

MEDALS. Numismatists have usually given the name of medals to those coins that have been struck or cast for particular purposes and on extraordinary occasions, in commemoration of victories, treaties, coronations, and similar important events, or in honour of remarkable persons, in distinction to those which have been issued and generally circulated as money.

The words *medaglia* and *medaglione* first occur in Italian writers, from whom the English and French have evidently taken their *medal* and *medaille*. The derivation seems to be from the Greek *μέταλλον* (metal), of which medals are always made.

A reference to medals, in connection with numismatics, has been made in the article on coins [COIN], to which a few observations must now be added respecting them independently of their relation to the general subject. Owing to the earlier writers on ancient coins considering them as medals, and not coins, the term knowledge of medals was applied to the study of numismatics. The Greeks struck no medals; but certain large coins of Syracuse, weighing from 668 to 680 grains of silver, dekadrachms, or pieces of 10 drachms, have been called erroneously by some numismatists *medallions*. They were, however, destined for circulation, like the 20 shilling silver coin of Charles I. in England, and the 100 zecchini gold of Ludovico Manin, doge of Venice, 1789-97. The first ancient medals, in the proper sense of the word, are the Roman brass *medallions* [NUMISMATICS], with which may be classed the brass pieces called *contorniat*, *spintrix*, &c. Gold and silver coins of unusual size and weight are also called medallions, and by some supposed to have been issued for commemorative purposes.

Among the peculiarities which distinguish modern from ancient medals, may be mentioned the introduction of portraits of illustrious characters who were not of princely or regal houses. It is remarkable that while busts are found of many celebrated poets, historians, and philosophers of antiquity, their portraits seldom occur on medals. When, after the long interval of darkness in which literature and art were enveloped, from the decline of the Roman empire to the 7th or 8th century, taste began again to appear, and, with the other arts, die-engraving revived, it was employed in transmitting to posterity the portraits of eminent individuals.

The first medals were the productions of painters and sculptors, and were made of lead or bronze, and cast in moulds of clay or fine sand taken from models of wax. The art was subsequently taken up by goldsmiths, and medals were made in repoussé work, or in chasing in the precious metals, or in bronze, a style of work which Carradosso and Cellini chiefly produced. At the beginning of the 16th century, in Germany, medals were made in boxwood or soapstone from which moulds were made: and the medals cast and chased by Albert Durer and other artists. At the beginning of the 17th century Camelio began to cut steel dies, a master mould, or model of raised steel, was made, and soft iron dies stamped from it. Cellini had previously used dies for small medals. About A.D. 1583 small enamelled medals were made by jewellers for ornamental purposes.

The earliest examples of modern medals and medallions seem to be of the 15th century, though there is one remarkable exception to this in a medal of David II., king of Scotland. It is of gold, and was probably executed during that prince's captivity in England, some time between the years 1330 and 1370. Another medal of A.D. 1371,

ARTS AND SCI. DIV. VOL. V.

of the Lord of Schornverst is also known. From the 15th century there is a succession of medals in most European countries. A gold medal of the council of Florence, dated 1439, is one of the earliest. A still earlier one, if the date 1415 is correct, is of John Huss; but some doubts have been entertained of its authenticity. Vittore Pisano, a painter of Verona, is celebrated as the restorer of the art at that period; but the medal alluded to of David of Scotland seems to prove that it was practised before his time. Pisano's medals are very large, and are all cast. They are usually inscribed "*Opus Pisani Pictoris*." It is curious that he should always refer to his being a painter, while exercising a totally distinct branch of art. Another painter, Boldu, in 1457 made a medal of the poet Mesararo.

The Papal medals are among the finest of a continued series. They commence properly with Paul II., who began to reign in 1464, those of pontiffs who lived prior to that date having been added to the collection by his successors. Till the age of Julius II. they were cast in moulds, and not struck. Some of the medals of a later period are valuable examples of the art, in which great improvements took place under Alexander VI. His successors, Julius II., Leo X., and Clement VII., had many of their medals designed by Raffaele and Giulio Romano, while Benvenuto Cellini and other distinguished artists were employed to engrave them. The medals of Julius III., in 1550, and of Gregory XIII., in 1571, were made by Covinio and Bassiano. Cormani, who engraved in 1644 a medal of Innocent X., having on the reverse Olympia Maidalchina, was imprisoned. Parmigiano engraved a medal of Gregory XIII., on the Restoration of the Calendar. Many of the Cinque-Cento medals are chased, as well as cast or struck. A German family, named Ermerani, or Hamerani, of eminence as medal engravers, settled in Italy about the middle of the 17th century, and executed many of the papal medals. This talent was not, it appears, confined to the men of this family; Venuti says each of the daughters also produced a fine medal. In later times Girometti and Cerbara are renowned.

The German medals commence in 1453, and are very numerous; the Emperor Maximilian I. and Rudolph II. employed Italian artists, but the German artists of Augsburg and Nuremberg acquired great celebrity. The Sicilian medals appear as early as 1501. The first modern satirical medal is of that time, and was published by Frederick II. against his adversary Ferdinand, king of Spain. It bears on one side the head of Ferdinand, with the inscription *FERDINANDVS R. AR. VETUS VULPES ORBIS*; on the reverse, a wolf carrying off a sheep, with *JUGUM MEUM SUAVE EST ET ONUS MEUM LEVE*. Many others might be mentioned of this description. The employment of medals for the conveyance of satire is not confined to the moderns. They are the precursors of the modern caricatures.

In Russia the taste for medals commenced with Peter the Great, and Maria Feodorowna the wife of Paul I., and Count Feodor Tolstoy, in the beginning of this century, engraved medals of considerable merit.

The Spanish medals begin in 1503. The earliest of Venice appear in 1509; and those of Denmark in 1474. The first Dutch medals seem to be of 1566, and they are remarkable for the elaborate views, maps, and plans that are engraved on many of them. It has been observed among the distinctions of ancient and modern medals, that in the former, when buildings are represented, the simple elevations only are given, while in the latter perspective views are exhibited. The Dutch indulged very freely in the satirical vein, and for which they eventually paid very dearly, as it contributed, in no small degree, to bring on them the whole hostile power of France under Louis XIV., who is said to have been highly exasperated at the publication of a medal in which Van Heubingen, the Dutch ambassador, was represented as Joshua (his name) arresting the progress of the sun, under which type the flatterers of Louis designated that monarch. Mueller, Pool, and Abeele were chiefly renowned.

The French medals commence with Louis XI., and reached high perfection in the reign of Francis I., who employed Cellini. The popularity of Louis XIV. gave an impulse to the art, and we find his entire life illustrated (with more respect, however, to the national glory and the prince's vanity than to historical truth) by medals; some of them are well designed and finely executed. The best engravers of these medals were Dupré, Varin, and Duvivier. The medallic history of Napoleon I. deserves notice in the series of medals of France. It is of great extent, and is, for the most part, honourable to French art. These medals, executed by Andrieu, Jeuffroi, Droz, and Manfredini, exhibit great classical taste and feeling, and contain a record of the events of the first empire. The reverses are generally allegorical. Many of them were executed from the designs of the celebrated Denon, and the painter David. One, struck in anticipation of the taking of London, is remarkably rare. In recent times Barré made fine medals for Louis Philippe.

The series of English coins and medals is one of the most perfect. The first medal is of 1480. It is of a large size, and is executed in the early Italian manner. On one side is a portrait of Sir John Kendal, general of cavalry of the order of Rhodes, with *IO. KENDAL. RHODI. TURCUPELLARIUS*; on the reverse, the arms of Kendal, with the inscription *TEMPORE OBSIDIONIS TURCORUM. MCCCCLXXX*. It is believed to be of foreign, probably Italian, workmanship. The next English medal is of the time of Henry VIII. It is of gold, and bears the king's

portrait on one side, with an inscription on the reverse. The first coronation medal appears in the reign of Edward VI. The medals of Queen Mary are numerous, and very interesting from the devices they bear. There are many fine and beautiful medals of Elizabeth. The Scotch coronation medal of Charles I. is of gold, and was struck at Edinburgh. Briot was the best artist of this reign. It is remarkable as being the first struck in Britain with a legend on the edge. Specimens of this medal in gold are very scarce. The medals of the Commonwealth and of Charles II. are by Simon, and by the Roettiers, Dutch engravers, who were succeeded by Croker, engraver in the reign of Anne. Those of Queen Anne are interesting from their being charged with the achievements of the great Duke of Marlborough. Soon after this a Genevese artist, of the name of Dassier, was employed upon the medals of the kings of England, and executed many portraits of royal and other illustrious characters. Natter, the celebrated gem engraver, made medals in the reign of George III. In recent times many admirable medals have been engraved by the Wyons, and Pistrucci, a celebrated gem engraver.

The only Oriental nation that appears to have issued medals at an early period is the Chinese, military medals having been used during the Han dynasty, A.D. 10, and being kept up till the present day. Few or no medals exist of Indian states, except the supposed gold medal of Jehanghir, A.D. 1611, representing that monarch holding a flower on one side, and the constellation Leo on the other, which is probably a coin; and the large piece of Shah Jehan, made at Delhi, A.D. 1617.

The study of medals is, in its class, of great importance. It is indispensable to the historian and the antiquary, and hardly less valuable to the man of taste. To the former, medals often afford information that cannot be obtained by other means, in the inscriptions, legends, and allegories with which they are charged; while to the artist and connoisseur many of them offer not only exceedingly beautiful examples of art, but, if their authenticity can be depended on, a series of medals of any nation is one of the best authorities that can be consulted for the state of the arts of design of any particular period.

Modern medals differ in their art and treatment greatly from the Roman medallions, the last representing a few political and religious ideas treated in an allegorical manner, while medals represent the busts of distinguished persons, or of allegorical personages, subjects treated in an allegorical manner derived from the antique, or various events represented in a pictorial rather than a glyphic manner—sieges, buildings, edifices, instruments, machines, and other objects of nature, art, or civilisation. Amongst the moderns, medals take the place of honorary rewards for merit, either in intellectual acquirements, military, civil, or social services, and have replaced the crowns, trappings, and torques presented by Greece and Rome to illustrious citizens. As early as Henry IV. of France, and during the 17th century, it became the practice for monarchs to present medals, having their portraits, attached to gold chains, to warriors, statesmen, and men of letters. Such chains and medals were presented by the Parliament in the days of the Commonwealth to Blake and his captains, and Elizabeth conferred similar rewards on those who aided to overthrow the Armada. While, too, the medallions convey little information beyond that imparted by coins, the range of subjects in modern medals will convey to posterity representations of buildings, inventions, and events probably long after all other knowledge of them has perished, and will prove invaluable aids to the future students of chronology, history, and the arts.

It would be an almost endless task to enumerate the works that have been written on medals. The principal works on modern medals are those of Menetrier, Fleuremont, Godennesche, Lenormant, and Millingen, for those of France; Van Loon has described those of Belgium and the Low Countries; Hedlinger and Brenner those of Sweden, Denmark, and Russia; Evelyn and Pinkerton those of England; Mazzuchelli, the Italian medals of the Cinque-Cento period; Klotz, the satirical pieces; and Koehne, some of Germany. See Bolzenthall, H., 'Skizzen zur Kunstgeschichte der Medaillen-Arbeit,' 8vo, Berlin, 1840.

MEDICINE. The earliest records of the practice of medicine are extremely obscure. Among the Jews it appears to have been entirely confined to the priests, and the whole art seems to have consisted in the prevention of contagion by isolation and cleanliness, and the administration of a few uncertain remedies. The Egyptians, according to the account of Herodotus, must have made some little progress; purging medicines and emetics were well known to them and much used; and such was the subdivision of labour, that there were physicians for every separate complaint, some for the eyes, others for the head, others for the teeth, others for the abdominal parts, and others for diseases which did not manifest themselves by outward visible symptoms. (Herod., ii. 84.) It appears however that in the time of Darius the son of Hystaspes, the Greeks possessed at least more skill than the Egyptians. (Herod., iii. 129.) The Greeks probably derived their knowledge of medicine, with that of many other arts, from Egypt, whence Chiron, the Centaur of their fables, is said to have first introduced it among them. His pupil Æsculapius [ÆSCULAPIUS, in BIOG. DIV.] so much improved the art, that he was deified; and Machaon and Podalirius, his sons, accompanied the Grecian army to the siege of Troy. From circumstances mentioned in the 'Iliad,' it would appear

that their practice was almost entirely confined to the treatment of wounds, and that charms and incantations formed a considerable portion of the means which they employed. The descendants of Æsculapius were for many years the chief practitioners of medicine: they were called Asclepiadæ, and were the priests of the temples erected in honour of their progenitor, to which the sick were accustomed to resort for advice and the application of remedies.

In the 6th century before the Christian era, medicine, with other sciences, began to be more philosophically studied in Greece, and among the first of those who devoted much of their time to the investigation of the structure and functions of the animal body was Pythagoras. His pupils Democritus and Heraclitus appear also to have added considerably to the knowledge both of anatomy and of practical medicine, and their contemporary Herodicus first introduced the practice of gymnastic exercises, which afterwards formed so large a part of medical treatment. [GYMNASTICS.] But the most remarkable man in the history of medicine in Greece was Hippocrates, one of the Asclepiadæ, who was born at Cos (where one of the chief temples was erected), B.C. 460, and was the pupil of Heraclitus and Herodicus. [HIPPOCRATES, in BIOG. DIV.] The improvements which he made in medicine (and many of which are detailed in the article referred to) were so considerable, that for many centuries his successors appear to have been content to follow him in reverential imitation. His sons, Thessalus and Draco, and his son-in-law Polybius, were the most renowned of his descendants, and they are generally regarded as the founders of the medical sect or school which was called the Hippocratic or Dogmatic sect.

The establishment of the Alexandrian school of philosophy forms the next most important epoch. The science of medicine was assiduously cultivated, and the human body was first dissected in Alexandria by Erasistratus and Herophilus. [HEROPHILUS, in BIOG. DIV.] The former was the pupil of Chrysippus, a violent opponent of the Hippocratic school, and a bold innovator in medicine, with whom probably originated the schism in consequence of which, for some centuries, every physician ranged himself in one of two sects, the Dogmatists and the Empirics. The Dogmatists held that disease could not be securely treated, except on the foundation of a knowledge of the healthy structure and actions of the body, and of the influence of remedies and the effects of disease upon it; while the Empirics maintained that such knowledge was not only unnecessary, but unattainable, and that simple experience should be the only guide to practice. The progress of the science was greatly arrested by the observation of facts being neglected in the ardour with which each party argued its own cause, and the dispute only seemed to cease with the introduction of a new sect.

During the early periods of the Roman empire medicine seems to have been little cultivated, and, according to Pliny (xxix. 1), Rome was for 600 years without professed physicians, though not entirely without medical knowledge. The first individual of any eminence who practised medicine in Rome was Asclepiades of Bithynia [ASCLEPIADES, in BIOG. DIV.], who lived in the century before the commencement of the Christian era; but he does not appear to have advanced the knowledge of the science. He was succeeded by his pupil Themison, the founder of a sect called Methodics, who held doctrines nearly intermediate between those of the Dogmatists and of the Empirics. A large majority of succeeding physicians attached themselves to this sect, and among them were Soranus and Aurelianus, whose writings are the principal that remain of this period.

About two centuries later the Methodics were divided into numerous sects, as the doctrines of particular physicians became more generally received. The chief of these sects were the Pneumatics and the Eclectics. The former are represented by their most eminent writer, Aretæus [ARETÆUS, in BIOG. DIV.], who lived in the reign of Vespasian, and the chief points of their doctrines are detailed in his life. Of the Eclectics, the most celebrated was Archigenes, of Apamea, who practised at Rome in the time of Trajan. But the most remarkable writer of this age was Celsus, in whose work, 'De Medicinâ,' the progress and condition of medicine previously to and during his life are amply detailed. [CELSUS, in BIOG. DIV.] He was the first native of Rome who is known to have studied medicine, and the only one who did so with success. In his time medicine, which, as a science, might be said to have had its origin with Hippocrates, had made considerable progress; the several sects of its professors differed rather in their pretensions than in any important point of knowledge; the philosophical learning, which some sought and others despised, was almost entirely hypothetical, and had relation only to the doctrines of the mutual actions of imaginary atoms, elements, and spirits, but all had been alike engaged in the study of practical medicine, and their accumulated experience had by this time formed a very considerable amount of useful knowledge.

The individual whose history forms the next chief epoch in the history of medicine is Galen; but it will be unnecessary to repeat what has already been said of his doctrines and practice. [GALEN, in BIOG. DIV.] For a long time after his death physicians were chiefly occupied in commenting on his works, and imitating, as closely as they could, his practice. His writings were regarded as ultimate authority, and everything that seemed opposed to them was at once rejected. From the time of Galen to the 7th century the only names of any

repute (and theirs is but small) are Sextus Empiricus, Oribasius, Aëtius, Alexander Trallianus, and Paulus of Aëgina; and after the death of the last of these, no medical work of the least merit was published in the Greek language.

From the 7th to the 12th century the only nation in which medicine made any progress, or was even prevented from retrograding, was the Arabian. It appears that on the conquest of Alexandria some books were saved from the burning of its magnificent library, and that among them were the writings of Hippocrates and Galen. The latter were soon translated into Arabic and diligently studied; and all the earliest Arabian works on medicine, as those of Ahrun in the 8th, and Serapion in the 9th century, are little more than transcripts of those of Galen. One of the most illustrious of the Arabian school was Rhazes [RHazes, in BIOG. DIV.], who was born in the 9th century, and whose works contain many original observations, of which the most remarkable relate to some important diseases, unknown to, or at least not described by former writers, as smallpox and measles. In those parts of his writings which relate to pharmacy Rhazes describes some of the earliest of what are called chemical remedies, which are doubtless suggested by the recent origin of the systematic practice of chemistry among his countrymen. After Rhazes was Ali-Abbas, and after him Avicenna [AVICENNA, in BIOG. DIV.], who attained the highest repute of all. He was born in 980, and has left voluminous writings, which however appear to show that his fame is deserved only when he is placed in comparison with his contemporaries. Neither Avicenna nor the later writers, Mesue and Albucasis, contributed anything of importance to the progress of medicine. Avenzoar and Averroes were disciples of the Arabian school, and, though natives of Spain, wrote in the Arabic language. The former was the preceptor of the latter, and lived in the 11th century, and his works are among the few that exhibit even slight departures from the doctrines of Galen. The circumstances which chiefly mark the period of the Arabian school of medicine are, the more correct description of several diseases, the first records of some new and important ones, and the introduction of several valuable remedies, both from the vegetable productions of the tropical and oriental countries, and from the chemical processes which were then first brought into general use. But the physicians adhered too carefully to the doctrines of Galen to make much progress in their science; and anatomy, physiology, and pathology appear to have been almost entirely neglected.

From the decline of the Arabian school in the 12th century to the beginning of the 15th, the history of medicine presents few circumstances of interest. The dissection of the human body was first publicly practised by Mondini at Bologna, about the year 1315; and at about the same time lived Gilbert, the first English writer on medicine who acquired any repute. Between the 12th and 15th centuries several of the most important universities were founded, with a school of medicine attached to each: that of Salerno was established in the 12th century, that of Montpellier in the 13th, those of Bologna, Vienna, and Paris in the 14th, and in the 15th those of Rome, Padua, Pavia, and several other cities in Italy. By means of these, and by the impetus which, with all other sciences, it received from the invention of printing, medicine again commenced a forward course. In this country it derived the greatest advantages from Linacre [LINACRE, in BIOG. DIV.] and the establishment of the College of Physicians, to whose members, in succeeding years, several of the most brilliant discoveries are due.

In the 15th century the sect of chemical physicians arose, and their doctrines, under the bold advocacy of Paracelsus, who publicly burnt the writings of Galen, obtained considerable credit and numerous supporters. Their main assertion was that the operations of the living body are entirely governed by the same chemical laws as obtain in inorganic matter; and the works of all the writers of the 15th century are filled with arguments in support either of this doctrine or of the more ancient tenets of Galen. The Galenists were of course the more learned party, who were well versed in the ancient books; while the chemists were chiefly those who were more practically skilled in the arts of that newly discovered science. Neither party can be said to have much advanced the knowledge of medicine; but in the middle of the 16th century the most important improvement commenced in the diligent and accurate study of anatomy by Vesalius [VESALIUS, in BIOG. DIV.], who, disregarding the general obloquy which he incurred, carefully studied the structure of the most important parts of the human body.

From the time of Vesalius, the study of anatomy was diligently pursued, and in the early part of the 17th century was rewarded by several of the most interesting and important discoveries; as that of the circulation by Harvey [HARVEY, in BIOG. DIV.], of the absorbents by Asellius, of the process of respiration by Malpighi [MALPIGHI, in BIOG. DIV.], and numerous others. Among the most celebrated men of the 17th century, may be enumerated Glisson, Bartholin, Rudbeck, Fabricius, Hooke, Sylvius, Willis, Riolanus, Fallopius, and Bellini. All of them were employed in the diligent pursuit of anatomical and physiological knowledge; and, somewhat later, Sydenham [SYDENHAM, in BIOG. DIV.] again introduced a truly Hippocratic mode of observation of the phenomena of disease in its symptoms, causes, and effects, and in the influence of remedies upon it. By the combined efforts of the anatomists and the practical physicians, medicine in this

century made the most remarkable progress, although it was in some measure checked by the attempted application of the laws of mechanics (then, from the discoveries of Newton and others, the dominant science) to the explanation of all the phenomena of the living body. The iatro-mathematicians, as those who supported this theory were called, were long engaged with the chemists, who had already conquered the Galenists; and to these rival sects was then added that of the Vitalists, founded by Van Helmont [HELMONT, VAN, in BIOG. DIV.], which at last obtained complete ascendancy over both. The Vitalists held that there is in the living body a principle (upon which different members of the sect conferred different hypothetical appellations) which presides over and directs all the processes of the living body, and is directly opposed to the influence of chemical and mechanical agents. Stahl, Hoffmann, and Boerhaave were of this school, though each considerably modified the opinions of its founder.

Among the pupils of Boerhaave were Van Swieten and Haller. [HALLER, in BIOG. DIV.] The former adopted the hypothetical spirit of the school too closely to add much of real value to medical science; but the latter may be fairly considered to have done more for it than any other single individual. Before the time of Haller, the cases of Harvey, Glisson, Malpighi, and others who devoted themselves to the simple observation of facts and the evident deductions from them, were exceptional; but since his time, the exceptions have rather been those who, with a comparative neglect of observation, have endeavoured only to find or support some theory by which all the phenomena they met with might seem explained. Haller's contemporary Cullen [CULLEN, in BIOG. DIV.], though he yielded much more to theory, was of eminent service in the study of practical medicine; and his opponent Brown is acknowledged to have introduced many useful lessons in the same branch of the study.

With the gradual oblivion of the hypotheses of both Cullen and Brown, the theoretical study of medicine may be considered to have entirely ceased, and in the present day we may certainly be said to be without any general medical theory. From the time of Haller, medicine has acquired more and more nearly the character of a science of simple observation and the patient investigation of facts. Its history would therefore consist of little more than a recital of successive discoveries, each perhaps small when compared with the vast amount of knowledge still unexplored, yet altogether so numerous that even a sketch of them could not be here introduced. The reader must therefore be referred to the several articles on the different branches of medicine and its collateral sciences, and to the lives [BIOG. DIV.] of those who have been most conspicuous for their discoveries.

MEDITATIO FUGAE WARRANT, in the law of Scotland, is a writ by which a debtor, supposed to be about to make his escape from the country, is arrested and kept in custody until he pay the debt, or find security to pay it if he shall be judicially found liable to do so. It may be granted by any judge having jurisdiction in questions of debtor and creditor, as by a sheriff, or the magistrates of a burgh. When granted by a sheriff, it has the advantage that it may be executed in any part of Scotland, whether without or within the jurisdiction of the sheriff who grants it.

MEDULLIN. A name given by John to the pith of the elder, after it has been treated with water and with alcohol. It is insoluble in water, alcohol, ether, oils, or dilute alkaline solutions; concentrated sulphuric acid carbonises it; nitric acid converts it into oxalic acid.

It is a modification of cellulose. [CELLULOSE.]

MEERSCHAUM means in German *sea foam*; and the equivalent French name of *écume de mer* is applied to the same substance. It is a silicated magnesian mineral, found in Greece, Turkey, and a few other countries. It is used by the Tartars for washing linen, somewhat in the same manner as pearl ash or fullers' earth. The mineral is principally used however as a material for tobacco pipes, which, when made, are soaked in melted tallow, then in white wax, and finally polished with shave-grass. If genuine, a meerschaum pipe acquires a beautiful brown colour after being smoked for some time, the oil of the tobacco being absorbed by the clay; and this is a point to which connoisseurs in smoking attach much importance.

Dr. E. D. Clarke gives some interesting details on this subject. In the Crimea the meerschaum clay is called *keff-kil*, and forms a stratum about two feet thick, beneath a much thicker stratum of marl. "The first rude form is given to the pipes upon the spot where the mineral is found; here they are pressed within a mould, and laid in the sun to harden; afterwards they are baked in an oven, boiled in milk, and rubbed with soft leather. In this state they go to Constantinople, where there is a peculiar bazaar or khan for the sale of them; they are then bought up by merchants, and sent by caravans to Pesth in Hungary. Still the form of the pipe is large and rude. At Pesth a manufacturer begins to fit them for the German markets. They are there soaked for twenty-four hours in water, and then turned in a lathe. In this process many of them, proving porous, are rejected. Sometimes only two or three out of ten are deemed worthy of further labour. From Pesth they are conveyed to Vienna, and frequently mounted in silver. After this they are carried to the fairs of Leipsic, Frankfort, Mannheim, and other towns upon the Rhine, where the best sell from three to five and even seven pounds sterling. When the oil of tobacco, after long smoking, has given them a fine porcelain yellow, or

which is more prized, a dark tortoise-shell hue, they have been known to sell for forty or fifty pounds of our money.

Since Dr. Clarke wrote, a change has taken place in the manufacturing arrangements. Rough Turkish bowls still occasionally come to market; but the meerschau is mostly sent to Germany in the form of irregular blocks, with obtuse angles and edges: requiring careful manipulation with the aid of water to remove irregularities and faulty portions. Many specimens contain a harder sort of meerschau, which the Germans call *kreidemassen*, and which is a cause of much difficulty in the subsequent carving. In order to economise the shreds and parings produced during the manufacture, they are brought to a fine powder, boiled in water, and moulded into blocks with or without the addition of clay. Each of these blocks is afterwards moulded and carved into a bowl. These bowls are distinguished from real meerschau by a greater specific gravity; but in other respects they are not easily distinguished.

Some large and fine specimens of meerschau are carved so elaborately into pipe-bowls, as to command two or three hundred guineas each.

MEGARIAN SCHOOL. After the death of Socrates the majority of his disciples retired to Megara ('Diog. Laert.' ii. 106, iii. 6), where Euclid, one of the oldest of them, resided. [EUCLID of Megara, in BIOG. DIV.] A few of these disciples remained at Megara with Euclid, who was looked upon as the founder of a school of philosophy which is usually known by the name of Megarian. In this school the Eleatic philosophy was taught, modified to some extent by the doctrines of Socrates. The Megarian philosophers maintained that the Supreme Good was always the same and unchangeable. They were distinguished in later times by their dialectic subtlety, and by the invention and solution of sophisms; on which account they were called Eristici (*ἐριστικοί*) and Dialectici (*διαλεκτικοί*). ('Diog. Laert.' ii. 106.)

The most celebrated of the successors of Euclid were, Eubulides of Miletus, who opposed certain opinions of Aristotle; Diodorus, surnamed Cronos, who was originally of Iassus in Caria, a pupil of Eubulides, and who lived in Egypt in the time of Ptolemy Soter; and Stilpo, who was originally of Megara, but afterwards resided at the court of Ptolemy Soter.

MELAIN, a name which has been given to the colouring matter of the ink of the cuttle-fish. It is obtained pure by evaporating the ink to dryness and boiling the residue successively in water, alcohol, hydrochloric acid, more water, and a little carbonate of ammonia. Dr. Prout found 100 parts of the dry residue of the ink of the cuttle-fish to be composed of—Melain, 78; carbonate of lime, 10.40; carbonate of magnesia, 7; substance analogous to mucus, 0.84; various salts, 2.16.

This substance has not been further investigated, and its existence as a distinct body must be regarded as problematical.

MELALEUCA CAJEPUTI (Roxb.), the *Melaleuca Minor* (Smith), a native of the Molucca islands, but cultivated in North-West India, yields the oil termed cajeput. It is obtained by distillation of the leaves and branches, which are collected the night before they are subjected to this process. It is very limpid, pellucid, and of a light or yellowish green colour. Specific gravity, 0.927; it boils at 343° Fahr. It is possessed of a penetrating odour; the taste is acridly aromatic, leaving a sense of coldness in the mouth. Its chemical composition is, carbon 78.12, hydrogen 11.49, oxygen 10.38. It seems to consist of two distinct oils: one transparent as water, of specific gravity 0.897; the second dark green, of specific gravity 0.920. Unrectified oil reddens litmus paper, but rectified does not. It does not detonate with iodine, nor does it form an artificial camphor with hydrochloric acid gas, but has its colour much changed by that gas. It never deposits a stearopten. Some samples of cajeput oil contain copper, which may be detected by shaking the bottle with a solution of ferrocyanide of potassium; an artificial oil is also sometimes vended, but it is not difficult to detect the fraud. It is an aromatic stimulant.

MELAM ($C_6H_6N_6 = 3NCyH_2$), *Poliene*. A compound substance discovered by Liebig. It may be prepared by simply heating sulphocyanide of ammonium, or a mixture of sulphocyanide of potassium and sal ammoniac; by their action there are produced three volatile products and a solid substance; the three first are ammonia, sulphuretted hydrogen, and sulphide of carbon; the solid body is a mixture of melam and chloride of potassium, which are easily separated by washing with water.

The properties of melam are:—It is a non-crystalline powder, of a grayish white colour, and is insoluble in water, alcohol, or ether; a boiling solution of potash dissolves and eventually decomposes it; boiling and concentrated nitric and sulphuric acid dissolve it, and the solutions, when treated with alcohol, produce a precipitate of ammelide; when the acid solutions are boiled for some hours, the melam is converted into ammonia and cyanuric acid.

By the action of heat melam is converted into ammonia and mellon: hydrochloric and dilute nitric acid convert it into ammeline and melamine; and when fused with hydrate of potash, ammoniacal gas and cyanate of potash are produced.

It is isomeric with cyanamide.

MELAMINE ($C_6H_6N_6 = 3NCyH_2$). One of the simplest processes for preparing melamine is to boil melam until it dissolves in a moderately strong solution of potash; when the liquor has been con-

centrated and cools, melamine separates in crystals, and by recrystallisation it is obtained in a pure state.

Its properties are:—It crystallises in rhombic octohedrons, which are transparent and colourless, or only slightly yellow. It is very slightly soluble in cold water, but more so in boiling water. It is insoluble in alcohol or in ether, and is unalterable in the air; the aqueous solution has a bitter taste, and has no action on vegetable colours. When dry melamine is heated, it fuses, and sublimes almost entirely without decomposing; but a small portion is converted into mellon and ammonia.

Concentrated sulphuric acid and nitric acid decompose it, when heated, into ammonia and ammelide or ammeline. When fused with hydrate of potash, there are produced ammonia and cyanate of potash.

It combines with dilute acids to form salts, all of which have an acid reaction except the double basic salts. The nitrate, phosphate, and oxalate are less soluble than the melamine itself; but the acetate and formiate are very soluble. Melamine precipitates a part of magnesia from solution, and forms a double salt with that which remains dissolved.

It is isomeric with cyanamide.

MELAMPYRIN, is a crystallised non-azotised substance obtained from the cow-wheat, *Melampyrum nemorosum*. It is a tasteless neutral principle.

MELANIC ACID ($C_{20}H_8O_{10}$). An organic acid resembling lamp-black in appearance, formed from hydride of salicyl. It is insoluble in water, but very soluble in alcohol, ether, and alkaline solutions.

MELANILINE ($C_{20}H_{13}N_3$). A cyanogen derivative of aniline.

MELANIN. The black pigment of the eye has received this name. It is insoluble in water, alcohol, and ether; but dissolves in caustic potash with disengagement of ammonia. It contains—

Carbon		57.54
Hydrogen		5.98
Nitrogen		13.77
Oxygen		22.71
		100.00

MELANOSIS is a malignant disease distinguished by the deposition of a peculiar soft morbid substance, of which the most prominent character is a deep brown or black colour. This substance may be deposited in separate masses, or infiltrated into the tissue of different parts of the body, or it may be effused from the blood in a fluid form into natural or morbidly formed cavities, or separated from it with the secretions. The deposition of melanotic matter generally takes place successively in numerous parts of the body, producing in all the injurious effects of compression and irritation, till it proves fatal either by its direct influence on some important organ or by the exhaustion which it gradually induces. [CANCER.]

MELANOXIMIDE. [OXAMELANILE.]

MELANURENIC ACID. A substance obtained by the action of heat upon urea. It is thought to be identical with ammelide.

MELANURIC ACID ($C_6H_4N_4O_4$). An organic acid, obtained by heating urea beyond its melting point:

MELASSIC ACID ($C_{24}H_{10}O_{10}$), is formed from cane sugar by the action of heat and alkalis. It has a very dark colour, and when thrown down by hydrochloric acid appears as a black flocculent deposit.

MELENE. [BEES'-WAX.]

MELINUM. [CADMIUM.]

MELISSIC ACID. [MELISSYL.]

MELISSIN. Synonymous with myricylic alcohol. [BEES'-WAX.]

MELISSYL ($\{C_{60}H_{59}O_2\}$). The hypothetical radical of melissic acid, one of the family of fatty acids, and obtained by treating myricylic alcohol with soda-lime. The silver salt of this acid has the formula $C_{60}H_{59}O_2 \{ Ag \} O_2$.

MELISSYLIC ALCOHOL. Synonymous with myricylic alcohol. [BEES'-WAX.]

MELITOSE ($C_{12}H_{22}O_{12} + 2Aq.$). A saccharine substance recently extracted from Australian manna.

MELLIC ACID. [MELLITIC ACID.]

MELLITIC ACID ($C_8O_6, 2HO$). A peculiar organic acid hitherto met with only in a rare mineral, the *honeystone*, or mellitate of ammonia. It is crystalline, reddens litmus strongly, and is not decomposed by boiling nitric or sulphuric acid. It has not yet been very completely examined.

MELLIMIDE. [PARAMIDE.]

MELLON ($C_{18}N_{13}$). The formation of crude mellon has already been noticed. [CYANOGEN, sulphocyanogen.] When it is fused with three times its weight of pure sulphocyanide of potassium a neutral mellonide of potassium is formed, which is very soluble in hot water, but which separates out on cooling in crystals, containing $K_3, C_{18}H_{13} + 10aq.$

From the formula of the above salt, it will be seen that mellon is a

tribasic radical. It has not been isolated in a state of purity, but its compound with hydrogen ($H_3, C_{13}N_{13}$) is readily obtained on passing sulphuretted hydrogen through a solution of mellonide of mercury in hydrocyanic acid. The sulphide of mercury is separated by filtration, and the hydrocyanic acid by the application of a gentle heat. The resulting solution of *hydromellonic acid*, or *hydromellon*, has a very acid taste and reaction, and decomposes the carbonates with effervescence. On evaporation, white flocks first separate, and a white slightly crystalline residue is ultimately obtained.

Neutral mellonide of potassium ($K_3, C_{13}N_{13} + 10 \text{ aq.}$), obtained as above, is converted into cyanuric acid by continued ebullition with hydrochloric acid. Heated with potash it is changed into CYAMELURIC ACID. Two other mellonides of potassium also exist. A monometallic salt containing $KH_2, C_{13}N_{13} + 6 \text{ aq.}$, and a bimetallic salt containing $K_2H, C_{13}N_{13}$.

Mellonide of silver ($Ag_3, C_{13}N_{13}$) is a white precipitate obtained on boiling neutral mellonide of potassium with nitrate of silver. *Mellonide of mercury* also is white, and obtained under similar circumstances with bichloride of mercury, and other mellonides may be produced in a similar manner.

MELODY ($\mu\epsilon\lambda\phi\delta\lambda\alpha$), in music, is Air or Song—a succession of single diatonic sounds, in measured time.

Melody and Air are synonymous terms in modern music, whatever their difference may have been in that of ancient Greece; we therefore shall add but little to what we have already said on the subject under the word AIR, to which the reader is particularly referred.

The question—which exercises most influence over the mind, melody or harmony? has often been agitated, Rousseau taking the lead, who certainly has treated it eloquently, but inconsistently, acting the part of advocate on both sides, and on each refutes himself. He seems to admit, and thus to agree with Metastasio, that music is a kind of language, but overlooks the fact, that, like every other language, it can only affect those who understand it by either studying its principles, as in the case of the few, or by frequently hearing, and thus becoming empirically acquainted with it, as in the case of the many. He does not seem to have considered that simple music, that is, melody, like simple language, makes most impression on the unlearned majority, because easily understood; while complex music, namely, harmony, like high-wrought rhetoric, excites more pleasure in the minds of the instructed minority, who enter into its combinations and perceive all its relations. Melody and harmony may be said to generate each other, the one being a selection of single sounds from a harmonic source, the other a union of two or more melodies simultaneously heard. Thus both are closely connected; and Dr. Burney has remarked, that after melody and harmony have been heard together, nothing can compensate for their separation.

MELOGALLIC ACID. [MELAGALLIC ACID.]

MELON (*Cucumis melo*) is an herbaceous, succulent, climbing or trailing annual, cultivated for its fruit in hot Eastern countries from time immemorial. In regions where most cooling vegetables disappear on the approach of great summer heat and drought, the melon, together with the water-melon (*Cucumis citrullus*), become essential substitutes. The antiquity of the cultivation of melons being so remote, and their dispersion over large portions of Asia and Africa so extensive, their indigenous locality cannot be traced at the present day. They were both introduced into England during the latter part of the 16th century, but it is not known whence.

If the roots be favourably situated, so far as moisture is concerned, the melon will bear a tropical heat; and, generally speaking, it will not succeed perfectly in the open air beyond the 43rd parallel of latitude. Its range of atmospheric temperature may be estimated at between 70° and 80° . The medium in which the roots are placed should of course be more uniform, and about 75° of bottom heat will be found both safe and efficacious.

Light is so essential, that unless the plants are kept near the glass, no tolerable degree of flavour will be acquired. As much of the direct rays of the sun should be admitted as the plants will endure, more especially when the fruit is approaching maturity. A screen may be occasionally necessary, but it should be of very thin texture.

If melon plants were not adapted for a dry atmosphere during a considerable portion of the day at least, they could not exist in the parching climates in which they naturally grow; and therefore a free admission of air is to be recommended, so far as is consistent with the maintenance of a high temperature. The health of the plant soon suffers if evaporation by the foliage is not freely carried on; for it is found that when it is obstructed by continued moist foggy weather, disease commences, and mildew ensues. The regulation of moisture in the artificial atmosphere in which melons are grown, under an English sky, is, of all others, the most insurmountable difficulty. Covering the soil with slates or tiles or with clean gravel has been successfully resorted to as a mode of preventing the air in the frame from being at all times saturated with moisture exhaled from the soil.

Melons will thrive if their roots are actually allowed to extend themselves in water; and in the case of the floating-beds on which they are grown in some parts of Persia, they find their way through the mould and its support into the water. But a drier medium for the roots becomes essential for good flavour in the comparatively close mode which in forcing them it is necessary to adopt in this country, in

order to prevent the dissipation of heat, which would otherwise take place from a limited atmosphere the temperature and elasticity of which are so much above that by which it is surrounded.

About four months may be allowed, on an average, when grown in pits, for the period between the sowing of melons and the ripening of the fruit. The middle of January is found to be early enough to sow; and the young plants are so exceedingly tender, that accidents are then very likely to occur to them. It is on this account necessary to make successive sowings, in order to be prepared for replacement, if requisite, and also for continuing the supply throughout the summer. A sowing for the latest crops will require to be made in April.

The seeds should be sown in shallow pans, and transplanted into small pots when their seed-leaves are about half an inch broad. It is best to put only a single transplanted melon into each pot. While this is done in a separate frame, that which is intended for their future growth and fruiting is prepared for their reception, by placing small hills, rather more than a foot high, of light rich mould below each sash, and nearer to the back of the frame than the front. Care must be taken that this mould be of the proper temperature before the young plants are introduced, which is to take place when they have made a few rough leaves. As the roots extend, more soil should be added of a gradually stronger nature; and ultimately the roots should have a depth of about 15 inches of such soil. When water is required, it should never be much below 70° , nor should it exceed 78° . It should not be applied when the air of the frame is at a high temperature from sun-heat. Shading is necessary immediately after watering, when the sun's rays have any great degree of power; unless this precaution is attended to, scorching will be induced, and the red spider will be likely to attack the foliage; other insects to be feared are aphides and thrips. The principal diseases to which melons are subject, are gum and canker. All are more frequent in the plants fruiting on hot-beds, than when treated as climbers.

With regard to pruning and training the *runners* or *vines* of melon plants, it is necessary that a sufficient number of these for filling the frame should be made to ramify as close to the base of the main stem as can be conveniently effected by pinching off the top of the latter when it has made a few joints, or four leaves above the cotyledons; and the laterals, which in consequence become developed, may be again subdivided by a similar process. Blossoms of a monœcious character will soon after make their appearance. The male blossoms, or at least a portion of them, must be retained for the purpose of fertilisation till the requisite quantity of fruit is fairly set, after which those shoots which have only male blossoms may be dispensed with, in order to afford more space for the foliage connected with the fruit. The extremities of the fruit-bearing vines are stopped by pinching at the second or third joint above the fruit. A piece of slate or tile is placed under each fruit for the purpose of keeping it from the damp soil. The heat must be fully maintained, or even considerably increased, as the fruit approaches maturity, in order to allow the admission of a more free circulation of air; but if at the same time the bottom heat be allowed to decline, the plants will become diseased and fall a prey to the mildew or to the red spider.

A very great improvement, however, in the mode of cultivation has been effected by the adoption of the plan of training them off the beds to trellises under glass-houses. The fruit has thus a better opportunity of ripening; and can frequently be cut a month earlier than if ripened on the bed; besides being less liable to damp or rot. The flavour is also finer. By this mode of cultivation, likewise, melons can be brought to fruit in winter, though they will then scarcely acquire the flavour given by a bright sun.

The varieties of melons can scarcely be kept permanent, particularly where many are cultivated, as they hybridise so readily. One of the finest is the Beechwood. Cuthill's Early Cantalope, Bromham Hall, Trentham, Green Fleshed Egyptian, and Green Fleshed Masulipatam, are esteemed excellent. Of the Persian varieties the Green Hoosainee, the large Germek, the Melon of Keiseng, Sweet Melon of Ispahan, and the Gerec, are the highest flavoured. The Dampsha is a winter melon. Of water-melons, the Spanish, the Imperial, and the Carolina are among the best.

(*Transactions of Hort. Soc.*; Loudon, *Encyclopædia of Gardening*; Mac Intosh, *Book of the Garden*.)

MELPOMENE. [MUSES.]

MEMOIRS, a term, in its application to a particular species of writing, of French origin, and in appearance properly signifying, as its obvious etymology would denote, a narrative or account mainly or primarily intended for no higher purpose than that of simply recording the facts it embraces, or addressing the one faculty of the memory. Perhaps the modern memoirs may be held to answer pretty nearly to what the Romans understood by *Commentarii* or *Commentaria* (see the meanings of this word in Facciolati, 'Lexic.'), unless when that title was given, in genuine or affected modesty, to writings of a more artificial character than that to which it rightly belonged. The philosophical ends, and the gratification of the imagination and the taste, aimed at in what is properly called a history, are not therefore to be looked for in memoirs, which, when they relate to historical subjects, are in truth not so much history as materials for history. A common description of French works of this kind is 'Mémoires pour servir' (that is, à l'histoire). Most frequently too, but not universally,

memoirs detail events in which the writer himself has been personally concerned. Very often the work is purely biographical, and not historical at all: and sometimes materials for biography only, and not a biographical work in the proper sense of the term. Sometimes it is neither historical nor biographical, but merely a discourse or statement on some point in science or literature; of this kind are the published memoirs of many academies ('Mémoires de l'Académie des Inscriptions,' for instance), and other literary or scientific societies. It may be noted, that when Horace Walpole wrote his amusing account of the last ten years of the reign of George II., probably soon after the middle of the last century, the word 'Memoires,' which is the title he has given his work, was still so far from being completely naturalised among us, that he has retained the French spelling. We have, however, several English memoirs—such for instance as 'Memoires of the Reign of King Charles I.,' by Sir Philip Warwick, 1701; 'Memoirs concerning the Affairs of Scotland,' by George Lockhart, Esq., 1714; 'Memoirs of John Ker, of Kersland,' by himself, 1726, &c. The French language is particularly rich in those kinds of historical and biographical materials which are expressed by the term *Mémoires*.

MEMORIAL. [ANNUITY.]

MEMORY is a name given to one of what are called the faculties of the mind,—the faculty (as it is otherwise expressed) of remembering or recollecting. The word is used to denote at the same time the operation or act of remembering, the state of the mind when it exercises the faculty, as distinguished from the faculty itself; but this last is a derived and by far the rarer use of the word.

What ideas are, how they are first generated, and how afterwards reproduced, are matters the explanation of which belongs to other articles. [ASSOCIATION; IDEA; SENSATION.] But when an idea is reproduced in the mind by any of the ordinary modes of association, and there co-exists with this idea the idea of its having been before present in the mind, this complex state of mind is a case of memory. We are then said to remember the thing (whatever it may be), the idea of which is thus present to the mind. This is an exercise of the faculty of memory.

Mr. Stewart seeks to make a distinction between the memory of events and the memory of things, on the ground that in the former case alone does the idea of past time form part of the complex state of mind. This does not seem to be correct. In all cases of memory, in the memory of things as well as of events, there is (as has been said) the idea of the idea which is now present to the mind having been present before. And this idea is obviously a complex idea, of which the idea of the previous time and the idea of the interval between that and the present time are parts. The particular idea of past time, by means of which Mr. Stewart seeks to make his distinction, belongs to the event that is remembered, and has evidently nothing to do with the mental phenomenon of memory. It is the idea of the event having taken place at a past time, and not (which alone is concerned with the mental phenomenon of memory) the idea of the idea of this event having been before present to the mind.

There is a distinction between *remembering* and *recollecting*, which, though not always observed in conversation, it is yet worth while to notice. The ideas that are remembered either come into the mind without any effort on the part of the person remembering, or with such effort. In the first case the person is more properly said to remember; in the second to recollect. The effort of recollection may be generally described as consisting in seeking out for different ideas which are likely to recall, by any of the ordinary modes of association, the desired idea. What these modes of association are has already been fully explained in two previous articles—ASSOCIATION and DREAMS.

It will be seen that the thing which is essential to the faculty of memory, and which distinguishes it from other faculties of the mind, that indeed which the faculty of memory may be said to be, is the faculty of recognising an idea which has before been present to the mind, as having been before present. But this faculty of recognition can never be exercised until the idea that is to be recognised has been introduced by one of the ordinary modes of association. Thus the principle or (as it may also be called) the faculty of association is necessary to the exercise of the faculty of memory. This principle of association, which, though necessary to the exercise of the faculty of memory, is yet only accidentally connected with that faculty, becomes consequently the basis of mnemonics, or the art of recollection.

The principle of all systems of mnemonics, however much these may differ in complexity, is the same, and simple. It is to select a number of objects which, whether of themselves or by reason of the order of selection, are more easily remembered than those which it is our object to remember, and to associate in our minds each one of the latter set with some one of the former. One of the simplest systems of mnemonics is the plan which used to be resorted to by the ancient orators, of connecting in their minds the different parts of a speech with different parts of the building in which it was delivered. The different systems of 'Memoria Technica' which have been put forth in later times are more complex specimens of the art. Of these, or any one of these, it is unnecessary to give a detailed account here. One of the best known is that of Dr. Grey (London, 1730); another is that by Feinagle.

MENDICITY. PAUPERISM.]

MENDIPITE. [LEAD.]

MENINGITIS is the term applied to that form of inflammation of the brain which affects the serous membranes by which it is surrounded. The following definition has been given of this disease. It is a complex morbid state of the immediate coverings of the brain attended with more or less vascularity and opacity of the arachnoid membrane, and the formation of adventitious products between the arachnoid and pia-mater, and the effusion of pus or serum in the same situation. Acute pain in the head accompanies these lesions, attended with intolerance of light and sound. There are present also watchfulness, delirium, a flushed countenance, and redness of the conjunctivæ, or heavy suffused state of the eyes. The pulse is quick, and there are frequent spasmodic twitchings or convulsions passing into somnolency, coma, and complete relaxation of the limbs.

This disease comes on at all ages. It attacks children during the period of teething, and comes on in scarlet fever, measles, and other diseases caused by morbid poison. It is then known under the name of acute hydrocephalus. [HYDROCEPHALUS.] Adults are liable to this disease as the result of typhus, typhoid, and paludal fevers. [FEVERS.] It also comes on as the result of accidents, of intemperance, great mental anxiety, and intense heat of the sun—"coup de soleil."

There is a great difference in the course and character of meningitis, according as it appears in a state of the system in which scrofula is present, and one in which this tendency is absent. Hence the disease is divided by some writers into simple and tubercular meningitis.

All forms of meningitis assume with more or less constancy three stages. 1. The stage of excitement resulting from the inflammation. 2. The stage of compression which indicates that effusion has taken place. 3. A stage in which the symptoms either pass from the last into that of health, or in which the disease progressively terminates in death. In each stage there is a distinct set of symptoms arising from the locality of the disease. The mental, sensorial, and motional functions are distinctly affected. In the first stage, the *mental* symptoms are either somnolence or wakefulness, or the one alternating with the other. There is delirium which is frequently of a furious character. In the second stage the delirium becomes quieter, or passes into coma, whilst in the third, the mental functions are entirely lost. In the first stage the most remarkable *sensorial* symptom is the intense and continuous pain in the head, which diminishes or disappears in the second stage; whilst in the third stage, complete anæsthesia takes place. The *motorial* symptoms of the first stage are restlessness, twitchings, and vomiting. In the second stage convulsions are frequently present, but in the third stage there is absolute paralysis of all the muscles.

The duration of these stages varies. Sometimes each lasts a week. The pulse in the first stage is from 90 to 100, in the second from 110 to 130, and in the last stage it is scarcely to be counted.

The symptoms of tubercular meningitis differ from those of the simple form, in their being generally less active. They occur in a state of the system which indicates to a greater or less degree the condition of tuberculous cachexia.

In the adult, the symptoms of meningitis have a tendency from the beginning to assume a convulsive or apoplectic character.

The treatment of this disease must in a great measure depend on the nature of the symptoms of the general disease with which it is associated. When it arises from mechanical injuries, it requires a more antiphlogistic treatment than when associated with blood disease. [HYDROCEPHALUS.]

Cerebritis or Encephalitis.—When the substance of the brain is affected independent of the surrounding membranes, the disease is called Cerebritis, or Encephalitis. This disease in its pure form is accompanied by very different symptoms from the first, the most distinguishing of which are the absence of headache and delirium. It consists in an inflammatory action of the vessels which supply the substance of the brain. It may however be combined with inflammation of the meninges, and then the symptoms of the attack are of a combined character. The lesions of the brain discovered after death in cerebritis, are a softening or suppuration of some part of the substance of the brain, which is frequently attended with a dusky redness.

The causes of inflammation of the substance of the brain are much the same as those of meningitis. It occurs at all ages, but adults are more liable to this form of disease than children, and old persons than adults.

There are two forms of this disease observed, the one acute and accompanied with a reddish appearance of the brain after death, the other more chronic, and accompanied with a white appearance of the brain after death.

The symptoms of this disease may be divided into the premonitory, those which are present during the attack, and those which remain after the acute symptoms have passed away.

The premonitory symptoms consist of a loss of mental vigour, a failure of memory, confusion of ideas, irritability of temper, and a sense of general weakness. There is a sense of heaviness, sometimes of heavy pain in the head, and tingling or numbness in the limbs, and often a loss of power in the muscles of one limb or one side.

During the attack the patient has mild delirium, which passes into a condition of insensibility, accompanied with great dulness of thought and perception. There may be an excited sensibility or an absence of

sensation. The muscles are either generally or partially paralysed, or there may be spasmodic contractions.

Should the attack continue, many of these symptoms may be relieved, but the functions of the brain are imperfectly performed, and the nervous and muscular functions are irregularly performed.

The treatment of inflammation of the substance of the brain, like that of inflammation of its membranes, must be determined by its causes. If it arises from mechanical injury, an antiphlogistic system must be pursued. If it accompanies the course of any disease produced by a morbid poison, the general symptoms must guide the treatment of the local disease. Where it comes on from mental distress, hard study, intemperance, or other causes, depletory measures must be pursued with great caution. In a large number of these cases a nutritious diet, with tonic medicines, are found to be most beneficial.

MENISCUS. [LENS.]

MENISPERMINE ($C_{18}H_{12}NO_2$) is a white fusible crystallisable alkaloid, forming salts with the acids found in the seeds of the *Menispermum cocculus*, known as *Cocculus Indicus*.

MENSTRUUM. A term used in chemistry to denote any liquid which is employed as the solvent of a body.

MENSURATION is the name given to a branch of the application of arithmetic to geometry, which shows how to find any dimension of a figure, or its area, or surface, or solidity, &c., by means of the most simple measurements which the case will admit of. We need hardly say that a complete treatise on this science would involve every branch of mathematical science. We shall in this article collect together the most important rules, the method of using which will be obvious to all who can employ the trigonometrical tables. By the length of a line we mean the number of linear units contained in it, and by its square and cube the number of units multiplied by itself once and twice.

The measurement of lengths and directions resolves itself for the most part into the determination of a side or angle of a triangle, when other sides or angles are given. The triangle may be either on a plane or on a sphere; but we refer the latter to SPHERE, since the use of spherical trigonometry can only be well explained in connection with astronomy. Let a, b, c be the sides of a triangle, and A, B, C the opposite angles. If the triangle be right angled at c , we have the following formulæ:—

$$a = c \sin A = c \cos B = b \tan A = b \cot B$$

$$b = c \sin B = c \cos A = a \tan B = a \cot A$$

$$c = \frac{a}{\sin A} = \frac{a}{\cos B} = \frac{b}{\sin B} = \frac{b}{\cos A}$$

$$c = \sqrt{a^2 + b^2} \quad a = \sqrt{c^2 + b^2} \quad b = \sqrt{c^2 + a^2}$$

The preceding formulæ contain the solution of every case of right-angled triangles.

We now pass to oblique-angled triangles, of which there are four cases.

1. Given the three sides, a, b , and c , to find the angles. Let the perpendicular let fall from c upon the longest side c divide it into two segments α and β adjacent to a and b , and let b be γa . Then the equations

$$\beta + \alpha = c, \quad \beta - \alpha = \frac{(b-a)(b+a)}{c}$$

(in which $\beta - \alpha$ is easily found by logarithms), will give β and α . Then

$$\cos B = \frac{a}{c} \quad \cos A = \frac{\beta}{b} \quad C = 180^\circ - (A + B)$$

Another method is as follows. Compute M from the following,*

$$s = \frac{a+b+c}{2} \quad M = \sqrt{\left(\frac{s-a}{s} \cdot \frac{s-b}{s} \cdot \frac{s-c}{s} \right)}; \text{ then}$$

$$\tan \frac{1}{2} A = \frac{M}{s-a} \quad \tan \frac{1}{2} B = \frac{M}{s-b} \quad \tan \frac{1}{2} C = \frac{M}{s-c}$$

2. Given two sides a and b , and the remaining angle c , required c, A , and B . Firstly, to find the angles, determine

$$\frac{1}{2} (B + A) \text{ from } \frac{1}{2} (B + A) = \frac{1}{2} (180^\circ - c)$$

$$(B - A) \text{ from } \tan \frac{1}{2} (B - A) = \frac{b-a}{b+a} \cdot \cot \frac{1}{2} c$$

$$A = \frac{1}{2} (B + A) - \frac{1}{2} (B - A); \quad B = \frac{1}{2} (B + A) + \frac{1}{2} (B - A)$$

$$c = b \frac{\sin C}{\sin B} = a \frac{\sin C}{\sin A}$$

* This convenient adaptation of a well-known formula is found, we believe, for the first time in Professor Wallace's work on Mathematical Theorems and Formulæ (Longman, 1839).

To find the third side without the aid of the angles, assume

$$\sin \theta = \frac{\sqrt{(ab) \cdot 2 \cos \frac{1}{2} c}}{a+b}, \text{ then } c = (a+b) \cos \theta;$$

or

$$\tan \theta' = \frac{\sqrt{(ab) \cdot 2 \sin \frac{1}{2} c}}{a-b}, \text{ then } c = \frac{a-b}{\cos \theta'}$$

3. Given a, b , and the angle A , to find the rest:

$$\sin B = \frac{b}{a} \sin A, \quad C = 180^\circ - (A + B), \quad c = \frac{a \sin C}{\sin A}$$

When $a < b$, B may be taken either acute or obtuse; and the problem has two solutions.

4. Given a , and two of the angles, to find the rest. It is unnecessary to distinguish the angles given, as two immediately determine the third.

$$b = a \frac{\sin B}{\sin A}, \quad c = a \frac{\sin C}{\sin A}$$

The area of the triangle is

$$\frac{ab \sin C}{2} \text{ or } \frac{bc \sin A}{2} \text{ or } \frac{ca \sin B}{2} \text{ or } \sqrt{(s \cdot s-a \cdot s-b \cdot s-c)}$$

The perpendiculars let fall from the vertices A, B , and c , upon the opposite sides, are severally $2 \sqrt{(s \cdot s-a \cdot s-b \cdot s-c)}$ divided by a, b , and c .

$$\text{Diam. of inscribed circle } 2 \sqrt{(s-a \cdot s-b \cdot s-c) \div s}$$

$$\text{Do. of circumscribed circle } \frac{a}{\sin A} \text{ or } \frac{b}{\sin B} \text{ or } \frac{c}{\sin C}$$

$$\text{or } abc \div 2 \sqrt{(s \cdot s-a \cdot s-b \cdot s-c)}$$

Segments of c made by perpendicular from c ,

$$\text{Adjacent to } a, \frac{c^2 + a^2 - b^2}{2c}; \text{ to } b, \frac{c^2 + b^2 - a^2}{2c}.$$

Segments of c , by line bisecting c ,

$$\text{Adjacent to } a, \frac{ac}{a+b}; \text{ to } b, \frac{bc}{a+b}.$$

$$\text{Line bisecting } c = \frac{2 \sqrt{(ab \cdot s \cdot s-c)}}{a+b} = \frac{2ab}{a+b} \cos \frac{1}{2} c$$

$$\text{Line bisecting } c = \frac{1}{2} \sqrt{(2a^2 + 2b^2 - c^2)}.$$

The area of a rectangle (in square units), and that of a parallelogram, is the product of the units in the base and perpendicular distance of the opposite sides. But if two sides only be parallel, half the sum of the parallel sides must be multiplied by the perpendicular distance between them. In other cases, the figure must be measured by dividing it into triangles, except when it is either a four-sided figure capable of inscription in a circle, or a regular polygon. Every triangle is half of the rectangle contained by any one of its sides, and the perpendicular let fall from the opposite vertex.

If a, b, c , and d be the sides of a four-sided figure inscribed in a circle, and s their half-sum, the area is

$$\sqrt{(s-a \cdot s-b \cdot s-c \cdot s-d)}.$$

If a be one of the sides of a regular polygon of n sides, the area of the figure and the diameters of the circumscribed and inscribed circles are

$$\frac{n a^2}{4} \cot \left(\frac{180^\circ}{n} \right), \quad a \div \sin \left(\frac{180^\circ}{n} \right), \quad \text{and } a \div \tan \left(\frac{180^\circ}{n} \right)$$

Tables connected with this subject are given in the article REGULAR FIGURES. For the method of measuring irregular areas, see QUADRATURES, METHOD OF.

The whole of the measurement of the circle depends upon the ratio of the circumference to the diameter, which is called π , and is 3.1415927 very nearly, or $\frac{22}{7}$ roughly, or $\frac{355}{113}$ very nearly. [ANGLE.] So many simple derivations from this number are practically useful, that we shall give a table of them, accompanied by their logarithms, first giving a method of multiplying and dividing by π , which is a correction of the use of $\frac{22}{7}$. To multiply by π , multiply by 22 and divide by 7; from the result take one-eighth of the hundredth part of the multiplicand as a correction; the result is too great only by about its 200,000th part. To divide by π , multiply by 7, divide by 11 and 2, and to the result add the eighth part of the thousandth part of the dividend; the result is too small by very nearly its 100,000th part.

The table just referred to is as follows:—

	Number.	Logarithm.
π	3.1415927	0.4971499
$\pi : 2$	1.5707964	0.1961199
$\pi : 4$	.7853982	9.8950899
$\pi : 6$	.5235988	9.7189986
$\pi : 8$	.3926991	9.5940599
$\pi : 12$	.2617994	9.4179686
$4\pi : 3$	4.1887902	0.6220886
2π	6.2831853	0.7981799
4π	12.5663706	1.0992099
$1 : 6\pi^2$	.01688686	8.2275490
$1 : \pi$	.3183099	9.5028501
$4 : \pi$	1.2732395	0.1049101
$1 : 4\pi$	.0795775	8.9007901
π^2	9.8696044	0.9942997
$\sqrt{\pi}$	1.7724539	0.2485750
$\sqrt[3]{\pi}$	1.4645919	0.1657166
$\sqrt{1 : \pi}$	.5641896	9.7514251
$\sqrt{4 : \pi}$	1.1283792	0.0524551
$\sqrt{1 : 4\pi}$	.2820946	9.4503951
$\sqrt[3]{6 : \pi}$	1.2407010	0.0936671
$\sqrt[3]{3 : 4\pi}$	.6203505	9.7926371
Hyp. log. π	1.1447299	0.0587030

To find the circumference from the diameter, multiply by π ; to find the diameter from the circumference, multiply by $1 : \pi$; to find the area from the diameter, multiply the square of the diameter by $\pi : 4$; to find the area from the radius, multiply the square of the radius by π ; to find the diameter from the area, multiply the square root of the area by $\sqrt{4 : \pi}$; to find the area from the circumference, multiply the square of the circumference by $1 : 4\pi$; to find the circumference from the area, multiply twice the square root of the area by $\sqrt{\pi}$; to find the ordinate perpendicular to a diameter, take the square root of the product of the segments into which it divides the diameter.

To find the area contained between two concentric circles, multiply the product of the sum and difference of the radii by π .

The arc of a circle and its subtended central angle are connected as follows: the arc which is equal to the radius subtends an angle of $57^\circ.3$ very nearly; or it may be easily remembered as 57 degrees and three-tenths of a degree, diminished by one-fourth of a minute and one-fifth of a second, being $57^\circ 17' 44''.8$, or $206264''.8$. To find an angle from its arc (the radius being known), multiply the arc by 57.3 , and divide by the radius; the result is too great by about three-quarters of its 10,000th part, and is in degrees and decimals of a degree. To find the arc from its angle, turn the angle into degrees and decimals, multiply by the radius, and divide by 57.3 : the result is now too small by about three-quarters of its 10,000th part.

To find the area of a sector, find the arc (if only the angle be given), and multiply it by half the radius. To find the area of a segment contained between an arc and a chord, find the sector, and from it subtract the triangle formed by the terminal radii and the chord. [SEGMENT.]

To find the length of an arc, when the radius is not known, measure the chord of the arc, and the chord of its half; from eight times the chord of the half subtract the chord of the whole, and take one-third of the remainder. For an arc not exceeding 60° , the error is less than the 7000th part of the whole.

The preceding are the principal rules of mensuration, of which the necessity occurs in the elementary parts of the subject: those which remain are connected with solid geometry, and the most essential are as follows:—

The number of cubic units in the content of a rectangular solid (or parallelepiped; there is no shorter term for this most elementary form of solid figures, unless the reader will follow us in calling it a *right solid*) is the product of the number of linear units in its three adjacent sides. The content of a prism or cylinder is the product of the number of square units in its base and the number of linear units in its altitude. The content of a pyramid or cone is one-third of the base multiplied by the altitude. The surfaces of a prism or pyramid must be found by computing those of their several faces. The surface of a common cylinder (not including the bases) or of a right prism is the circumference of the base multiplied by the altitude; that of a common cone is half the product of the circumference of the base and the slant side.

The following formulæ relate to the sphere. To find the surface from the radius, multiply the square of the radius by 4π , or the square of the diameter by π ; to find the content from the radius, multiply the cube of the radius by $4\pi : 3$, or the cube of the diameter by $\pi : 6$; to find the radius from the surface, multiply the square root of the surface by $\sqrt{1 : 4\pi}$; to find the diameter, multiply the square root of the surface by $\sqrt{1 : \pi}$; to find the radius from the content, multiply the cube root of the content by $\sqrt[3]{3 : 4\pi}$; to find the diameter, multiply the cube root of the content by $\sqrt[3]{6 : \pi}$; to find the surface from the content, multiply the cube root of the square of six times the content by $\sqrt[3]{\pi}$; to find the content from the surface, multiply the square root of the cube of the surface by $1 : 6\sqrt{\pi}$. [SPHERE.]

For other formulæ and methods, the detached articles on the different subjects may be consulted; or Hutton's or Bonnycastle's

elementary works on mensuration. Many works on mensuration have been published of late years.

MENTHA PIPERITA (Peppermint), a plant common in many parts of Britain, but cultivated for medical purposes. The dried plant, which is more powerful than the fresh, is of a lively green, with a peculiar aromatic odour, and a pleasant camphor-like taste, at first burning, but at last causing an enduring sensation of cold in the mouth. The dried herb is used for the preparation of a distilled water, and of a volatile oil, from which oil spirits or essence of peppermint is prepared. Of the oil several varieties occur in commerce, the German, English, American, and Chinese. Twenty pounds of the herb yield from four to six drachms; but if the flowers be also distilled, the same weight will yield four ounces. It is often adulterated with oil of turpentine, oil of marjoram, and absolute alcohol. When pure it is of a whitish yellow, yellow, or even green colour; odour very strong, taste burning, camphor-like, causing a sense of coldness in the mouth. The oil is at first limpid, but becomes thicker, like a fixed oil. European oil does not deposit a stearopten, but the American easily forms long colourless four-sided prisms, which possess the odour of the oil. The American oil is more soluble in alcohol than the German; specific gravity 0.92, but when rectified 0.90. The Chinese variety consists almost entirely of a stearopten. The action on the human system of any of the preparations of mint is stimulant and antispasmodic. The oil is used to be added to drastic or griping purgatives, and in other cases. It proved of considerable utility in bringing about reaction in the collapsed stage of Asiatic cholera.

MENTHA PULEGIUM (Pennyroyal), an indigenous species of mint, smaller than most of the others, and of which the entire herb, except the root, is officinal. The odour is strong and peculiarly aromatic; taste herbaceous and bitterish. It has a stimulant and antispasmodic property, similar to most mints, but is supposed to possess also a specific power over the uterus, which has been much overestimated. A distilled water, a spirit, and volatile oil are prepared from it, as from the *Mentha piperita*. A popular compound called hysteric water, consists of the distilled water of pennyroyal, and compound spirit of bryony, a very unsafe mixture.

MENTHA VIRIDIS (Spear-mint), a plant of Britain, very much resembling *M. piperita*; the colour however is of a deep green. It is also frequently confounded with *M. Crispa*, than which it has a stronger and more agreeable odour, but weaker than peppermint. It has not the aromatic odour of that plant, nor does it leave the sense of coolness in the mouth. From it are prepared a distilled water, a spirit, and a volatile oil, which are used as the former.

MENTHENE ($C_{20}H_{38}$). A hydrocarbon produced by the action of anhydrous phosphoric acid upon concreted essential oil of mint. It is a transparent fluid oil, possessing an agreeable odour.

MENU. [MANU.]

MENUIE. [COLOURING MATTERS.]

MENYANTHES TRIFOLIATA (bog-bean, corrupted into buck-bean, *Marsh Trefoil*,—officinal part, the leaves), a plant common in our bogs, and hence called bog-bean, as its leaves resemble the common bean. The leaves are ternate, petiolate, and even when dried have a fine green colour, but are without odour; they possess an enduring bitter taste. One hundred parts of the fresh herb dry into thirty-nine; ten pounds of the dried plant yield two pounds and three-quarters of extract. It contains an extractive (Menyanthin), which Brandes says forms a white, transparent, and, when highly dried, pulverisable mass of an intense degree of bitterness. Trommsdorff says he obtained only a yellowish brown, clear, very viscid, not pulverisable, bitter extract.

It is a tonic and febrifuge medicine of undoubted efficacy, but greatly neglected in the treatment of disease. The chief use said to be made of the large quantity annually collected is to substitute it for hops in brewing, a proceeding which is both illegal and detrimental to the beer, since, though bitter, it does not possess the aromatic quality of the hop.

MENYANTHIN is a non-azotised uncrystallisable neutral principle found in the common buck-bean, *Menyanthes trifoliata*.

MEPHITIC AIR. [CARBONIC ACID.]

MERCANTILE MARINE. [SHIPS.]

MERCAPTANS. Chemists apply this name to a series of sulphur-alcohols; that is, alcohols in which the oxygen is replaced by sulphur. The relation of the alcohols to the mercaptans will be most clearly seen by the following comparison of the formulæ of vinic alcohol and mercaptan.

The mercaptans are produced by saturating an alcoholic solution of potash with sulphuretted hydrogen, and then distilling it with the chlorine compounds of the alcohol radicals. Thus vinic mercaptan is produced by the following reaction:

Vinic mercaptan, which was the first investigated and most important of these compounds, and is frequently called *mercaptan*, gives the name to the series. The mercaptans are colourless liquids, possessing a horribly foetid alliaceous odour. They act like acids upon metallic oxides, forming *mercaptides*. This is especially so in the case of oxide of mercury, hence the origin of the name—*mercurium captans*. The following are the chief known mercaptans:

Methyl mercaptan	C_2H_5	$\left. \begin{array}{c} \text{H} \\ \text{H} \end{array} \right\} \text{S}_2$
Ethyl mercaptan	C_4H_9	$\left. \begin{array}{c} \text{H} \\ \text{H} \end{array} \right\} \text{S}_2$
Amyl mercaptan	$\text{C}_{10}\text{H}_{21}$	$\left. \begin{array}{c} \text{H} \\ \text{H} \end{array} \right\} \text{S}_2$

MERCURIAMINE. [MERCURY.]

MERCURY (Hg.) Quicksilver. The history of this well-known metal, a description of the sources whence it is obtained, its physical properties, and a list of the minerals in which it occurs have already been given under MERCURY, in NAT. HIST. DIV. An interesting statistical account of the most important of all the mercury mines, namely, those of Almaden in Spain, is also given under ALMADEN in GEOG. DIV. It is here, therefore, only necessary to treat of its chemical properties and the action of various substances upon it by virtue of which compounds of the metal are obtained.

The equivalent of mercury is 200. By combining with one or with two equivalents of other bodies it forms two classes of salts, known as *protosalts* and *bisalts*. Sometimes the equivalent of mercury is assumed to be 100, and then the first class of salts containing two such equivalents to one of another body are necessarily termed *disalts* or *subsalts*; while the second class, containing only one such equivalent to each equivalent of another body, are consequently termed *protosalts*. This want of uniformity in the nomenclature of salts of mercury is to be deprecated, inasmuch as it is confusing to students, and has also frequently led to serious errors when employed by those who, like medical men and compounders of medicine, have necessarily but a partial knowledge of chemistry. A method now very generally adopted, by which the inconvenience is obviated, consists in adding to the word *mercur* the terminals that are commonly used for similar purposes—namely, *ic* and *ous*. The first or lower class of salts are thus mercurous salts, and the second, or higher, mercuric salts.

Mercury and oxygen form two compounds.

1. Protoxide of mercury HgO
2. Binoxide of mercury HgO₂

1. *Protoxide of mercury (HgO). Black oxide, grey oxide, suboxide, or dioxide, of mercury. Mercurous oxide.* This oxide is best obtained by triturating calomel with dilute caustic potash or soda, and well washing and drying the resulting oxide. The operation should be conducted as much as possible in the dark, as the oxide is decomposed by the influence of light, into metallic mercury and binoxide. Though itself unstable, it forms very stable salts, called *salts of mercurous oxide* or shortly, *mercurous salts*.

2. *Binoxide of mercury (HgO₂). Peroxide, red oxide, yellow oxide, or protoxide, of mercury. Mercuric oxide.* This oxide may be made in several ways. The alchemists used to keep mercury at a boiling heat for a month, or longer, in a matrass, or a flask with a tolerably long neck, but having free communication with the air. It thus slowly absorbed oxygen, becoming converted into binoxide and was called by them *mercurius precipitatus per se*. It is now however generally prepared by calcination from mercuric nitrate when it has a bright orange colour, and is in the state of shining crystalline grains. Sometimes it is precipitated from a solution of a persalt of mercury by caustic potash or soda; it then differs from the crystalline variety in being converted into oxalate of mercury by the action of oxalic acid.

Binoxide of mercury darkens in colour when heated, but again becomes red on cooling. When ignited it is resolved into metallic mercury and oxygen gas. Chlorine acts upon it, especially when moist, hypochlorous acid and an oxychloride of mercury being formed. Reducing agents also readily attack it. It is a powerful base forming *salts of mercuric oxide*, or shortly, *mercuric salts*.

Mercury and sulphur form two sulphides corresponding to the two oxides:—

1. Protosulphide of mercury HgS
2. Bisulphide of mercury HgS₂

1. *Protosulphide of mercury (HgS). Mercurous sulphide. Ethiop's mineral.* This compound is precipitated when sulphuretted hydrogen is passed through a solution of a mercurous salt. It is also frequently made by triturating two hundred parts of mercury with sixteen of sulphur. It is almost as unstable as the protoxide.

2. *Bisulphide of mercury (HgS₂). Mercuric sulphide. Cinnabar. Vermilion.* This is the most common ore of mercury. [MERCURY, in NAT. HIST. DIV.] It is largely used as a pigment, but for this purpose

ARTS AND SCI. DIV. VOL. V.

is usually prepared artificially. The Chinese are very successful manufacturers of vermilion: the following is supposed to be the process they adopt. One hundred parts of mercury and thirty-eight of sulphur are triturated for two or three hours; twenty-five parts of solid caustic potash and one hundred and fifty of water are then added, and the whole heated to about 115° Fahr. for several hours. It must be constantly stirred at first, and, when the desired tint is obtained, removed from the fire and well washed with cold water.

In this country vermilion is commonly made by triturating mercury with about one sixth of its weight of sulphur, and then subliming. The beauty of the tint is said to depend upon the amount of levigation to which the sublimate is afterwards subjected.

Protosulphide of mercury is also thrown down when sulphuretted hydrogen gas is passed through a solution of a mercuric salt. It is black, but may be made to assume a red colour by sublimation. It is insoluble in aqueous solutions of the alkalies and in all acids except aqua regia. It is dissolved however in hydrochloric acid when arsenic or antimonious acids and some other oxidising agents are present.

Mercury and iodine form:—

1. Protoiodide of mercury HgI
2. Sesqui-iodide of mercury Hg₂I₃
3. Biniodide of mercury HgI₂

1. *Protoiodide of mercury (HgI). Green, or diniodide of, mercury. Mercurous iodide.* Prepared by triturating an equivalent of mercury with one of iodine, the mixture being moistened with a little alcohol to keep down the temperature and consequently prevent too rapid action and decomposition. It is also precipitated when a mercurous salt is mixed with solution of iodide of potassium. It is somewhat unstable.

2. *Sesqui-iodide of mercury (Hg₂I₃). Mercurous-mercuric iodide.* Precipitated when a solution of iodine in iodide of potassium is added to a solution of mercurous nitrate. Alcohol extracts no mercurous iodide from this compound—a proof that it is not a mere mixture of mercurous and mercuric iodide.

3. *Biniodide of mercury (HgI₂). Mercuric iodide.* Prepared as the protoiodide, two equivalents of iodine being used, or by precipitation from a mercuric salt by iodide of potassium. It is at first salmon-coloured, but by molecular alteration speedily becomes a magnificent scarlet. It sublimes in yellow tabular crystals, but on rubbing, scratching, or merely agitating, undergoes the alteration just mentioned and becomes scarlet; in short, biniodide of mercury is, in crystallographic language, dimorphous. During the change heat is evolved.

Double salts of biniodide of mercury with other compounds of mercury and with the alkaline iodides may be easily formed.

Mercury and bromine form compounds very much resembling the iodides.

Mercury and chlorine form two important chlorides:—

1. Protochloride of mercury HgCl
2. Bichloride of mercury HgCl₂

1. *Protochloride of mercury (HgCl). Subchloride or dichloride of mercury. Mercurous chloride. Calomel.* This compound of mercury has been known for nearly three centuries. It was first called *calomel* (from καλός, good, and μέλας, black) by Sir Theodore Turquet de Mayenne, though for what reason is not satisfactorily known. It occurs native [MERCURY, in NAT. HIST. DIV.] but for use in medicine is always prepared artificially. This is sometimes accomplished by adding chloride of sodium to a solution of a mercurous salt, and well washing and drying the precipitate. More usually, however, it is obtained by submitting to the action of heat a mixture, in equivalent proportions, of chloride of sodium and protosulphate of mercury; double decomposition takes place, protochloride of mercury sublimes and sulphate of soda remains. If the vessel in which this operation is conducted be small, the calomel condenses in brilliant quadrilateral prisms terminated by four-sided pyramids; but if the receiver be capacious, and especially if it be filled with steam, the calomel condenses in the form of an exceedingly fine white or slightly buff-tinted powder. By the latter modification of manufacture the trouble of grinding is avoided.

Calomel is tasteless and insoluble in water. The fixed alkalies convert it into protoxide. Ammonia changes it to *black precipitate* or *mercurous amidochloride* (HgCl + HgNH₂). It is very soluble in strong solutions of alkaline salts, but much less so in dilute solutions; decomposition into metallic mercury and mercuric salt accompanies the solution.

2. *Bichloride of mercury (HgCl₂). Perchloride of mercury. Mercuric chloride. Corrosive sublimate.* This compound may be formed by the direct union of its constituents, but is usually prepared by submitting to an elevated temperature a mixture, in equivalent proportions, of bisulphate of mercury and chloride of sodium. The following equation exhibits the reaction:—

Corrosive sublimate crystallises in white needles or in a semi-vitreous mass. It has an acrid, peculiarly metallic taste that is very unpleasant. It is soluble in three parts of boiling, and eighteen to twenty of cold water. Hot alcohol dissolves its own weight of this salt, and cold alcohol one-third of its weight; ether also readily dissolves it: indeed,

agitation with ether will abstract corrosive sublimate from an aqueous solution.

Double salts of bichloride of mercury with alkaline chlorides readily crystallise out when a solution containing them is evaporated. *Sal alembroth* is such a double salt containing $(\text{HgCl} + 3\text{NH}_4\text{Cl})$. It crystallises in flat tables.

White precipitate $(\text{HgCl}_2 + \text{Hg}_2\text{NH}_2)$ is thrown down when ammonia is added to a solution of corrosive sublimate.

Mercuric oxychlorides, containing two, three, or four equivalents of binoxide to one of bichloride, are precipitated when bicarbonate of potash and bichloride of mercury are brought together under various conditions.

Mercury and Cyanogen form only one salt, viz.:

Bicyanide of mercury (HgCy_2) . *Mercuric cyanide*. Usually made by boiling bisulphate of mercury with half its weight of ferrocyanide of potassium and four times its weight of water. It crystallises out in white needles on cooling the solution. It may also be made by dissolving binoxide of mercury in hydrocyanic acid, or by boiling Prussian blue with binoxide of mercury.

Bicyanide of mercury is soluble in alcohol and in eight parts of cold water; but in a much smaller quantity of boiling water. Its solution is very poisonous, and is neither precipitated by alkalis nor by any metallic salts, except those of palladium. By heat it is converted into metallic mercury and cyanogen gas.

There are two *sulphates of mercury* :—

1. Protosulphate of mercury HgO, SO_3
2. Bisulphate of mercury $\text{HgO}_2, 2\text{SO}_3$

1. *Protosulphate of mercury* $(\text{HgO}, \text{SO}_3)$. *Sub- or di-sulphate of mercury*. *Mercurous sulphate*. Formed on triturating bisulphate of mercury with as much mercury as it already contains. It is but slightly soluble in water.

2. *Bisulphate of mercury* $(\text{HgO}_2, 2\text{SO}_3)$. *Persulphate of mercury*. *Mercuric sulphate*. A mixture of two parts of mercury and three of sulphuric acid is boiled to dryness, when a white crystalline powder remains of the above composition. Water decomposes it into an acid salt $(\text{HgO}_2, 6\text{SO}_3)$ that remains in solution, and a yellow basic salt $(3\text{HgO}_2, 2\text{SO}_3)$, called *turpeth mineral*, which is precipitated.

There are many *nitrates of mercury*. The two most important are :—

1. Protonitrate of mercury HgO, NO_5
2. Binitrate of mercury $\text{HgO}_2, 2\text{NO}_5$

1. *Protonitrate of mercury* $(\text{HgO}, \text{NO}_5 + 2\text{Aq.})$. *Sub- or di-nitrate of mercury*. *Mercurous nitrate*. Formed by digesting metallic mercury in excess of cold dilute nitric acid. It crystallises in transparent prisms. Water decomposes it into a yellow, basic, insoluble salt, and an acid soluble salt. If excess of mercury is used in the preparation, crystals are obtained containing $(4\text{HgO}, 3\text{NO}_5 + 2\text{Aq.})$.

2. *Binitrate of mercury* $(\text{HgO}_2, 2\text{NO}_5 + \text{Aq.})$. *Pernitrate of mercury*. *Mercuric nitrate*. Best obtained by dissolving binoxide of mercury in nitric acid. It may also be made by dissolving mercury in boiling nitric acid, but it has not then a constant composition.

Chromates of mercury. An alkaline chromate throws down a bright red precipitate from a solution of a mercurous salt. It contains $4\text{HgO}, 3\text{CrO}_3$. Heated with nitric acid, it is converted into HgO, CrO_3 . *Mercuric chromate* is also a red powder precipitated when an alkaline chromate is added to a solution of a mercuric salt.

Fulminate of mercury. [FULMINATING MERCURY.]

Acetates of mercury. There are two :

1. Protoacetate of mercury $\text{HgO}, \text{C}_4\text{H}_3\text{O}_3$
2. Binacetate of mercury $\text{HgO}_2, 2\text{C}_4\text{H}_3\text{O}_3$

1. *Protoacetate of mercury* $(\text{HgO}, \text{C}_4\text{H}_3\text{O}_3)$. *Sub- or di-acetate of mercury*. *Mercurous acetate*. Precipitated in micaceous scales, when a soluble acetate is added to a strong solution of a mercurous salt. It is insoluble in alcohol, and decomposed by heat.

2. *Binacetate of mercury* $(\text{HgO}_2, 2\text{C}_4\text{H}_3\text{O}_3)$. *Peracetate of mercury*. *Mercuric acetate*. Made by dissolving binoxide of mercury in excess of hot acetic acid, or by mixing hot solutions of acetate of potash and binitrate of mercury, a little acetic acid being also added. It crystallises in white, inodorous, flexible scales.

Mercuramine is the provisional name given to a very powerful base, produced on agitating precipitated binoxide of mercury with solution of ammonia in a well stoppered bottle. It contains $2\text{HgO}_2, \text{NH}_3, 2\text{HO}$, and may be viewed as the hydrated oxide of $\text{HgO}_2, \text{HgNH}_2$. It is a white powder, very unstable, decomposing when exposed to light, or with a series of slight explosions when triturated in a mortar. It absorbs carbonic acid from the air as quickly as slaked lime does, and forms definite salts with acids.

Mercury with chalk is a preparation used in medicine. It is made by rubbing chalk and mercury together until the latter is so minutely divided as not to be perceptible by the naked eye. It is sometimes called *gray powder*, and from exposure to light is very liable to contain protoxide and binoxide of mercury.

Mercury with magnesia is a preparation similar to that just described. The mixture of the two is facilitated by the introduction of a little manna, which is subsequently got rid of by washing with water.

Other preparations containing finely divided metallic mercury are also used in medicine. Such are the pill, ointment, and cerate of mercury.

Tests for mercury. The salts of mercury are distinguished by being volatilised by heat, and by yielding globules of metal when heated with carbonate of soda in a narrow test tube. From solution the metal is precipitated with its characteristic appearance on to a piece of gold (such as a half-sovereign) when the liquid is rubbed on the gold with a key or other piece of steel. Metallic copper also causes the deposition of mercury from solution with characteristic lustre. Protochloride of tin has the same effect. Sulphuretted hydrogen throws down a black precipitate.

Proto- or mercurous salts are distinguished by turning black on the addition of an alkali. From solution, hydrochloric acid throws down a white precipitate (calomel), and iodide of potassium a green precipitate.

Per- or bi- or mercuric salts give no precipitate with hydrochloric acid, a yellow (binoxide) with fixed alkalis, white with ammonia, and scarlet with iodide of potassium.

Estimation of mercury. This is usually effected in the metallic form. It is brought to this state either by protochloride of tin, or by heating with quick lime in a glass tube through which a current of hydrogen is passing, the mercury being collected in a glass bulb.

Sometimes mercury is precipitated by sulphuretted hydrogen, and estimated in the state of bisulphide. In that case it is always advisable to wash the sulphide with sulphite of soda solution, which has the effect of dissolving any free sulphur.

MERCURY-ALLYL. [ORGANOMETALLIC BODIES.]

MERCURY-ETHYL. [ORGANOMETALLIC BODIES.]

MERCURY-METHYL. [ORGANOMETALLIC BODIES.]

MERCURY, Medical Properties of. In a purely metallic state, mercury, when taken into the human stomach, produces no effects except such as are owing to its mechanical properties; such as when it is improperly employed to remove the obstruction of the bowels in lead, or painters', cholic. Nevertheless it may become oxidised, and, by combining with some of the acids of the stomach, occasion violent disorder. Even its external application leads to similar results, from the metal first becoming oxidised, then absorbed, and producing the same effects as if taken by the mouth. The preparations of mercury differ very much in the degree of their action, both according to the nature of the combination, and also of the dose employed or the mode of administration. The milder preparations seem only to increase the natural and healthy actions of the organs of the body, particularly the secreting and exhaling organs; while the more active, if not given in very minute doses, destroy the texture and impair the function of many organs, both those with which they are brought into immediate contact, and others which they affect by sympathy or other means. No medicinal substance is capable of producing so much benefit, none is so frequently abused, or so fertile a source of injury, as mercury. Its mode of action is little understood, but its effects are often sufficiently obvious. A brief statement of the most important of these effects is all that can be given here.

When mercury, triturated with chalk or magnesia, or with confection of roses (which is the case when it is made into *blue pill*), is taken in moderate dose into the stomach, it does not seem to make any immediate sensible impression, unless that organ be in a state of morbid sensibility, when it is apt to cause heartburn, nausea, or disturbance of the bowels. It may be repeated at proper intervals, and the individual, especially if robust, appears only to have an increased appetite and more ready digestion. This is more particularly the case when corrosive sublimate (bichloride of mercury) is given in very minute doses. Even the introduction of mercury into the body by friction over parts where the skin is thin, would seem to increase for a time the activity of the whole system. To whatever surface applied, the absorbents would appear to lay hold of it, and carry it into the circulating mass. Owing to peculiarity of constitution (idiosyncrasy) a very minute quantity of mercury produces in some individuals very striking effects, either violent salivation, disturbance of the bowels, or other inconveniences, accompanied by great debility. This result is quite distinct from the effects of an overdose of some of the more active forms, which produces actual poisoning, or from the effects of the too long continued administration of some of the mild preparations. Children, owing to the irritability of their bowels, are not so apt to be salivated as adults, and more mercury can be borne in warm than in cold countries.

When a single dose of mercury is given, it is generally one of the preparations which act on the bowels, either alone, or in combination with or followed by some other purgative medicine, and little permanent effect is observed; but repeated small doses, especially if hindered from passing off by the bowels, by combination with opium, excite arterial commotion, and end by establishing a febrile movement. The pulse is full and more frequent, the animal heat augmented, the secretion from the skin abundant, at last followed by thirst, restlessness, and sleeplessness. This disturbance frequently lasts some time, even after the medicine has been discontinued, and is occasionally accompanied with determination or congestion of blood either towards the lungs, abdomen, or brain, followed sometimes by hæmorrhage from various organs. Blood drawn during a mercurial course is generally found covered with a buffy coat, the same as is the case in inflamma-

tory diseases. On the salivary glands the effects are most conspicuous; they become irritated, more sensible, turgid, and pour out abundant saliva, which, on standing, deposits flakes of coagulated albumen. The breath at the same time acquires a peculiar fetor (called mercurial); the gums are swollen, with a peculiar line running along the margin, but pale and tender; the teeth become loose; and the tongue and lining membrane of the mouth are covered with ulcers.

The general commotion of the system often proves a powerful agent in the cure of many diseases; but occasionally it becomes too great, and requires to be moderated. Not only must the exhibition of the mercury be suspended for a time in such cases, but very plethoric persons must be bled, and put on the antiphlogistic plan even before beginning its use. The warm bath, diluent drinks, and a milk or farinaceous diet, with cool air, are proper means of lessening the violence of its action. Iodine is said to have the power of expediting the removal of the mercury out of the system.

The effects just mentioned show the necessity of abstaining from its administration when there is a tendency to hæmorrhage (especially of the lungs), or a disposition to consumption, or if there exist a scrophulous constitution, or the person be affected with sea scurvy; also during certain states of the female system, and during pregnancy or suckling.

When the use of mercury is too long continued, or it is given in too strong doses, its stimulating action appears to fatigue the system, and to pervert the function of assimilation, both immediately in the blood and also in the different organs and tissues. Hence the individual loses his muscular power, becomes pale, tumid, and puffy, or else greatly emaciated. The brain and spinal chord are irritated; the limbs exhibit involuntary tremblings, such as are observed in the workers in the mercurial mines, in makers of looking-glasses, and other trades in which mercury is largely used; and all the tissues acquire a morbid susceptibility. The blood is found to be deteriorated, and to have lost its ordinary consistence, and the person appears to be affected with scurvy or consumption. The inconsiderate use of mercurial preparations, especially of corrosive sublimate, often occasions chronic inflammation of the stomach, causing indigestion, and alterations or thickenings of the coats of the stomach. Diseases of the brain not unfrequently result from an improper use of mercury. Lastly, a peculiar affection of the skin often occurs from the abuse of this substance.

In the treatment of diseases, four distinct effects may be obtained from the employment of mercurial preparations. 1. By some of them the intestinal canal is irritated, and the expulsion of its contents occasioned. 2. Others are used to create a general commotion of the system, to rouse the lymphatics, and excite both the secreting and excretory glands. 3. To control or altogether change the action of the capillary vessels, when that is extreme and tending to the effusion of serum, and more especially of coagulable lymph. With this may perhaps be joined the action of the mercury as an alterative. 4. What is regarded as its specific effect in bringing about the cure of some peculiar diseases.

Calomel, or the protochloride of mercury, is the preparation most employed as a purgative; it influences the intestinal canal along its whole length, and excites the liver and other glands to secretion. It is of very great utility, not only at the commencement of fevers, but even during their course, either when given alone or in conjunction with some other purgative. It is not admissible if the tongue be very red and sensible, and a similar state of stomach be presumed to exist. In many eruptive fevers, especially scarlet fever, its early and even free employment is productive of the best results. In the yellow and many other fevers of hot climates it is indispensable. In these diseases, mercury is introduced into the system by every means; and whenever the patient is salivated recovery may be expected. In many of the less rapid fevers of Europe the like benefit follows its use.

During the inflammatory and turgescient stage of hydrocephalus acutus, or water on the brain, calomel, alone or with digitalis, is frequently efficacious in saving the patient; at the same time other forms of mercury, especially the liniment, may be used. In the wasting or atrophy of children, the steady daily use of calomel and rhubarb produces the best results, if proper dietetical means be adopted.

These measures should at no time be resorted to except under the direction of responsible medical attendants. The unnecessary use of mercury, when some other purgative would have answered as well, is much to be reprobated, and not only injures the constitution of children, but, if they are teething at the time, it leads to the early decay of their teeth. (Bell 'On the Teeth'.)

Persons under the influence of mercury, even when a single dose has been taken as a purgative, are very liable to take cold, especially from wet. This must be carefully guarded against. The bichloride of mercury (or corrosive sublimate) seems not to dispose the system so much to be hurtfully impressed by cold, and is therefore well suited to camp and navy practice. Besides, if given in sufficiently small doses, it is perhaps the best of all the preparations to use as an alterative, especially in cases of chronic inflammation or thickening of the tissues, such as the heart. This particular preparation of mercury seems to exert a beneficial effect in restraining the escape of the albumen of the blood by the kidneys, in the disease called albuminuria, or Bright's disease. It should be given in very minute doses, the $\frac{1}{10}$ th of a grain,

dissolved in distilled water, about half an hour after each meal. If any signs of salivation manifest themselves it should instantly be suspended. Indeed from time to time it should be discontinued, as no system can bear the continuous use of mercury.

Mercury has a great power of checking the deposition of coagulable lymph, and controlling changes in the organic particles of bodies, both vegetable and animal. One of the most valuable uses of mercury is connected with this power of changing the action of the capillaries when that action is extreme, or when there is a tendency to pour out serum in excess, or effuse coagulable lymph. In some inflammations the action of the vessels is so violent as to pour out their contents, and this leads to obstructions or changes of structure which derange the functions, or even speedily occasion death. Thus, in croup, coagulable lymph is effused in the windpipe, obstructing respiration; in peritonitis, or inflammation of the outer lining of the intestines, lymph is poured out, agglutinating the folds of the intestines; in iritis the same happens, closing the pupil of the eye and destroying vision. In all these cases, after free venesection, or even without it, calomel given very freely will hinder further effusion, and even cause the absorption of what has already escaped from the vessels, as may often be seen when the iris of the eye is inflamed.

Many serious chronic diseases are removed by a judicious and persevering use of mercury; but these can neither be enumerated here, nor can even the most general rules be attempted to be laid down. (Holland, 'Medical Notes'; 'On Mercurial Medicines'; and Teale, 'On Neuralgic Diseases'.)

The specific employment of mercury is still less suitable to be discussed here. It may be remarked, however, that the opinion for the necessity of giving mercury in any quantity is now altogether exploded.

It is not necessary to dwell on any of the other preparations of mercury, many of which are valuable, either alone or as additions to other substances. Calomel frequently greatly assists in promoting the action of other medicines, particularly diuretic medicaments. How far calomel, either in small frequently repeated doses or in very large ones, was really useful in Asiatic cholera, cannot be ascertained. But where it has been given, and salivation has occurred, or the mercurial fetor of the breath perceived, recovery has almost invariably ensued. The employment of corrosive sublimate in the arts depends in some cases on principles explained above. Thus it checks fermentation, and opposes the formation of new compounds: hence, when applied in solution to timber, it prevents the dry-rot from occurring by solidifying the albumen of the wood. [ANTISEPTICS.] In cases of poisoning by it, the antidotes most proper are those substances which contain albumen, such as white of egg, milk, flour, &c. [ALBUMEN.] (See 'Observations Relative to the Science and Art of Medicine,' by William Wegg, M.D., London, 1851.)

MERCURY, the planet nearest to the sun. Its orbit being entirely within that of the earth, it never recedes to the point of the heavens opposite to the sun, but is always found within 29° of the sun. Hence it is only visible to the naked eye in the evening, when it is to the east of the sun, and near to its greatest distance (or elongation) from the sun; so that the sun can descend sufficiently below the horizon to allow the planet to be seen just before its setting: similarly, it is only visible in the morning (before sunrise), when it is near its greatest elongation westward of the sun. The phases of Mercury are not visible without a telescope. The apparent diameter of Mercury varies from 5 to 12 seconds; the real diameter is $\cdot 398$ of that of the earth, or about 3140 miles. Its bulk is to that of the earth as 63 to 1000; its mass is reckoned at the two-millionth part of that of the sun. It revolves on an axis, the inclination of which to the ecliptic is not determined, in $24^h 5^m 28^s \cdot 3$. It has seven times the light and heat of the earth.

The transits of Mercury, or passages of the planet over the sun's disc, take place when the conjunction (the inferior conjunction, as it is called, Mercury being between the earth and the sun) happens at the time that the planet is near its node. These transits are not so useful in the determination of the sun's parallax or the longitude of the place of observation as those of Venus: we shall therefore refer the account of such transits in general to the latter planet. The following are, according to Delambre, the times of the transits which will yet take place in the present century (civil time at Paris):—

1861 12 Nov., $7\frac{1}{2}$ A.M.	1881 8 Nov., 1 A.M.
1868 5 Nov., 7 A.M.	1891 10 May, 3 A.M.
1878 6 May, 7 P.M.	1894 10 Nov., $6\frac{1}{2}$ P.M.

Elements of the Orbit of Mercury.

Epoch, 1799, December 31, 12^h mean astronomical time at Seeberg.

Semimajor axis $\cdot 3870938$, that of the earth being assumed as the unit.

Excentricity $\cdot 2041704$; its secular increase (or increase in 100 years) $\cdot 0000039$.

Inclination of the orbit to the ecliptic $7^\circ 0' 5'' \cdot 9$; its secular increase $18'' \cdot 4$.

Longitudes from the mean equinox of the epoch: (1.) of the ascend.

ing node, $45^{\circ} 57' 9'' 0$; its secular increase (combined with the precession), $4215'' 1$; (2.) of the perihelion, $74^{\circ} 20' 6'' 0$; its secular increase (combined with the precession), $5602'' 9$; (3.) of the planet (mean), $108^{\circ} 4' 48'' 3$.

Mean sidereal motion in one mean solar day, $4^{\circ} 5' 32'' 558$; in 365 $\frac{1}{4}$ it is $53^{\circ} 42' 47'' 85$ more than 4 complete revolutions; sidereal revolution, 87.96926 mean solar days.

MERCURY, TRANSIT OF. [MERCURY; VENUS.]

MERCURY, DEPRESSION OF. [BAROMETER.]

MERGER. It is somewhat difficult to give an exact definition of this legal term. In order to form an accurate notion of what is meant by it, the notion of the legal term estate [ESTATE] is a necessary preliminary. "The accession of one estate to another, or, more accurately speaking, the circumstance that two estates immediately expectant on each other, meet or are united in the same person, is the cause of the merger." (Preston.) These words express in general terms the conditions necessary in order that merger may follow as a consequence. This consequence, called merger, is that the preceding estate ceases to exist, and the estate in which this preceding estate is said to be merged continues to be exactly the same as it was before that union which was the cause of merger.

It is necessary to add to this general description of the cause of merger, that the estate which is prior in point of time must not be greater (in legal estimation) than the estate which immediately follows: it may be either equal or less, but not greater. Also the estates must both be vested estates, and both must be legal or both equitable estates.

Thus, if A is tenant for life, with reversion to B in fee, and A surrenders his estate to B, or B releases his estate to A, in either case the life-estate is merged, the consequence of which is that the estate in reversion immediately becomes a fee in possession. It seems that one term of years will merge in another, and a larger term in a less: at least this is the case when the second term is a term in reversion. Thus, if A is tenant for years, with reversion to B for years, and A surrenders or assigns his term to B, the term which belonged to A is merged. There is one exception to this rule: if the estate of A is derived from the estate of B as an underlease, the original term of B is not abridged by such merger. In fact, merger, in the proper sense of the term, can never apply to a surrender or assignment of an estate in land to the person by whom, and out of whose larger estate that smaller estate was granted. But if A who is seised in fee, leases first to B for five hundred years, and then to C for ten years, by way of immediate reversion, and C assigns his term to B, the estate of B is merged in that of C, which becomes an estate in possession, and can have no longer duration than ten years. Opinions vary as to the question whether a term can merge in a term in remainder.

Estates tail are not subject to merger; an exception which is a necessary consequence of the form of the gift to the heirs in tail, so long as there are any. Formerly, if an estate tail had become a base fee by the tenant in tail levying a fine, such base fee would merge by union with the immediate reversion in fee. But by a recent statute (3 & 4 Wm. IV. c. 74), such base fee will not merge in the reversion in fee, but shall be "enlarged into as large an estate as the tenant in tail, with the consent of the protector, if any, might have created by any disposition under this Act, if such remainder or reversion had vested in any other person."

If the two estates, the union of which in one person might otherwise cause merger, do not unite in him in the same right, there is no merger.

The various exceptions to the general principles of merger are numerous enough to form the subject of an entire treatise. The whole subject is discussed at great length in the third volume of Mr. Preston's 'Treatise on Conveyancing.'

The origin of the doctrine of merger is uncertain, and no hypothesis seems fully to explain all the cases of merger as now settled. In the case put by Bracton (fol. 12), the termor for years who had become the feoffee of the land, is considered as having, by the acceptance of the freehold, renounced the term (ex quo idem B se tenuit ad feoffamentum, tacite termino renuntiavit). The origin of merger is discussed in Preston's third volume, chap. iii., &c.

MERIDIAN (*meridies*, mid-day). In the heavens the meridian is the circle which passes through the pole and the zenith of the spectator: on the earth it is the circle which passes through the pole and the spectator's position; consequently the terrestrial meridian is the section of the earth made by the plane of the celestial meridian.

The circle derives its name from being that on which the centre of the sun is found at mid-day, or real noon. In the case of a fixed star, the time at which its altitude is greatest is the moment of its coming on the meridian; but in that of the sun or a planet, the orbital motion prevents the moment of its culmination (or coming on the meridian) from being exactly that of its attaining its highest point; though the difference is not worth noting for ordinary purposes. [SPHERE, DOCTRINE OF THE.]

MERLON. [EPAULEMENT.]

MESACONIC ACID ($C_6H_6O_9$) *Citracaric Acid*, is an acid described by Gottlieb, and obtained by the action of nitric acid on

citraconic acid. It forms minute crystals, sparingly soluble in water. [CITRIC ACID.]

MESITE. One of the constituents of wood naphtha. It is a very mobile fluid, boiling at 158° Fahr., and possessing an ethereal odour. *Mesitene* is another similar fluid obtained from wood naphtha, and boiling at 145° Fahr.: both are soluble in 3 parts of water.

MESITENE. [MESITE.]

MESITYL-HYPOPHOSPHOROUS ACID ($C_6H_6O_2, HO, PO$). This acid, along with *mesityl-phosphoric acid* ($C_6H_6O_2, HO, PO_3$) and *mesitic aldehyde* ($C_6H_4O_2$), are obtained by certain reactions with acetone; their composition cannot be considered as established.

MESITYL-PHOSPHORIC ACID. [MESITYL-HYPOPHOSPHOROUS ACID.]

MESITYLOLE ($C_{18}H_{12}$), is obtained from the distillation of acetone with fuming sulphuric acid. Thus, 3 equivalents of acetone = $3(C_6H_6O_2)$, yield 6H O and mesitylole. The atoms of hydrogen may be substituted by chlorine, bromine, and nitrous acid.

MESMERISM, the term usually applied to the phenomena of animal magnetism, after the name of its first propounder, Anton Mesmer. (MESMER, in BIOG. DIV.) Perhaps the time is not yet come when the combined physiological, pathological, and psychological phenomena of mesmerism can be rationally explained. At any rate it involves a series of facts in relation to the human system which historically have a high interest. Not that these are all new since the time of Mesmer; but he first gave a systematic character to the phenomena, and, with the air of a philosopher, sought to refer them to scientific principles. The following is his account of the agent which he supposed to exist:—

"Animal magnetism is a fluid universally diffused; it is the medium of a mutual influence between the heavenly bodies, the earth, and animated bodies; it is continuous, so as to leave no void; its subtilty admits of no comparison; it is capable of receiving, propagating, communicating all the impressions of motion; it is susceptible of flux and of reflux. The animal body experiences the effects of this agent; by insinuating itself into the substance of the nerves it affects them immediately. There are observed, particularly in the human body, properties analogous to those of the magnet; and in it are discerned poles equally different and opposite. The action and the virtues of animal magnetism may be communicated from one body to other bodies, animate and inanimate. This action takes place at a remote distance, without the aid of any intermediate body; it is increased, reflected by mirrors; communicated, propagated, augmented by sound; its virtues may be accumulated, concentrated, transported. Although this fluid is universal, all animal bodies are not equally susceptible of it; there are even some, though a very small number, which have properties so opposite, that their very presence destroys all the effects of this fluid on other bodies. Animal magnetism is capable of healing diseases of the nerves immediately, and others mediately. It perfects the action of medicines; it excites and directs salutary crises in such a manner, that the physician may render himself master of them; by its means he knows the state of health of each individual, and judges with certainty of the origin, the nature, and the progress of the most complicated diseases; he prevents their increase, and succeeds in healing them, without at any time exposing his patient to dangerous effects or troublesome consequences, whatever be the age, the temperament, and the sex. In animal magnetism nature presents a universal method of healing and preserving mankind." (*Mémoire sur la Découverte du Magnétisme Animal*, par M. Mesmer, Paris, 1779, p. 74, et seq. *Ibid. Avis au Lecteur*, p. 6.)

The mode adopted by Mesmer of bringing the magnetised under the influence of the magnetic fluid was peculiar. In the middle of each room in which the persons to be treated were collected was placed a large circular vessel, made of oak about a foot or a foot and a-half in height: the interior of this vessel was filled with pounded glass, iron filings, and bottles containing magnetised water arranged symmetrically: the cover or upper part of the vessel was pierced with numerous holes, in which were placed polished iron rods of various lengths, bent, and capable of being moved: this was called the *baquet*, or magnetic tub. The patients were placed in successive rows around the baquet, and each had one of the rods of iron, the end of which he applied to the part of his body which was supposed to be the seat of his disease: a cord passed around their bodies united the patients to one another, and sometimes they formed a second chain by taking hold of each other's thumbs. A pianoforte was placed in the corner of the room, and various airs were played upon it, sometimes accompanied with the sound of the voice and song. The magnetiser held in his hand a polished and pointed rod of iron from ten to twelve inches long. The baquet was a reservoir of magnetic virtues; its interior arrangement was for the purpose of concentrating the magnetic fluid; the rods were the conductors for transmitting it. The cords around the bodies of the patients and the other chain of connection by the thumbs were for increasing the effects of the fluid by communication. The magnetiser had previously charged the pianoforte with magnetic fluid; the person playing on it was incessantly giving out more; the sound conducted it to the patients. The purpose of the music was to put the patients into a state of quiet; to give them agreeable sensations, and thus to dispose them to receive the magnetic action. The purpose of the magnetiser's rod was to concentrate to a point the fluid which issued from him, and

thus to render it more powerful. The sick persons arranged in great numbers and in several rows around the baquet, thus receive the magnetism by all these means; by the iron rods which convey to them that of the baquet; by the cords wound round their bodies; by the connection of the thumbs which communicate to them that of their neighbours; by the sound of the pianoforte or of an agreeable voice diffusing the magnetism in the air; by the finger and rod of the magnetiser moved before their faces, above or behind their heads, and on the diseased parts, always observing the direction of the poles; by the eye of the magnetiser; but above all by the application of his hands and the pressure of his fingers on the hypochondria and on the regions of the abdomen; an application often continued for a long time, sometimes for several hours. Meanwhile the patients in their different conditions present a varied picture. Some are calm, tranquil and experience no effect: others cough, spit, feel slight pains, local or general heat, and have sweatings; others again are agitated or tormented with convulsions. These convulsions are remarkable in regard to the number affected with them and to their duration and force; and are characterised by the precipitous involuntary motions of all the limbs and of the whole body, by the constriction of the throat, by the leaping motions of the hypochondria and the epigastrium; by the dimness and wandering of the eyes; by piercing shrieks, tears, sobbing, and immoderate laughter. They are preceded or followed by a state of languor and reverie, a kind of depression, and even drowsiness. The smallest unforeseen noise occasions shudderings; even a change of tone and measure in the airs played on the pianoforte influences the patients, a quicker motion agitating them more and renewing the vivacity of their convulsions. Nothing is more astonishing than the spectacle of these convulsions; one who has not seen them can form no idea of them. The spectator is equally astonished at the profound repose of one part of the patients and the agitation of the rest; at the various accidents which are repeated and the sympathies which are established. Some patients devote their exclusive attention to each other, rushing towards one another, smiling, speaking with affection, and mutually soothing their *crises*. All are under the power of the magnetiser; it matters not in what state of drowsiness they may be—his voice, a look, a gesture brings them out of it.

Such is the account of M. Bailly, who, together with Lavoisier, Franklin, and other distinguished men, were appointed by the French government to examine into these splendid pretensions. These commissioners report—"That this pretended agent certainly is not common magnetism, for that, on examining the baquet, the grand reservoir of this wonderful fluid, by means of a needle and electrometer, not the slightest indication of the presence either of common magnetism or of electricity was afforded; that it is wholly inappreciable by any of the senses or by any mechanical or chemical process; that they tried it upon themselves and upon many others without being able to perceive anything; that on blindfolding those who seemed to be most susceptible to its influence, all its ordinary effects were produced when nothing was done to them but when they imagined they were magnetised, while none of its effects were produced when they were really magnetised, but imagined nothing was done; that, in like manner, when brought under a magnetised tree nothing happened if the subjects of the experiment thought they were at a distance from the tree, while they were immediately thrown into convulsions if they believed they were near the tree, although really at a distance from it; that, consequently, the effects actually produced were produced purely by the imagination; that these effects, though some cures might be wrought, were not without danger, since the convulsions excited were often violent and exceedingly apt to spread, especially among men feeble in body and weak in mind, and almost universally among women: and finally, that there were parts of the operation of magnetising which might readily be turned to vicious purposes, and that immoral practices had already actually grown out of them."

Notwithstanding such a report from men so well qualified to form a judgment, animal magnetism continued to flourish to such a degree, that Dr. Franklin, writing some time after this report had become public, and adverting to the proneness of mankind to credulity, states that Mesmer was at that time getting more money in the shape of fees than all the regular physicians in Paris put together. Mesmerism in this form did not become popular in England. There was at one time some danger of it, but it was prevented by the skilful management of a physician of eminence. A man of the name of Perkins had invented a wonderfully convenient instrument for collecting, condensing, and applying animal magnetism, composed of a metallic substance, and called the metallic tractor. For this instrument he had obtained a patent, and its virtues he set forth in a work bearing the following title—"The Efficacy of Perkins's Patent Metallic Tractors in various Diseases of the Human Body and Animals; exemplified by two hundred and fifty cases from the first literary characters in Europe and America. With a Preliminary Discourse in Refutation of the Objections made by Interest and Prejudice to the Metallic Practice." Dr. William Falconer, of Bath, having made tractors of wood so exactly resembling the patent tractors that it was impossible for the eye to distinguish between the one and the other, tried, in conjunction with Dr. Haygarth, the effect of these fictitious tractors on a large scale on patients in the Bath Hospital, and produced precisely the same effects with the fictitious as with the genuine,

affording a demonstration that whatever effects were produced, were produced solely by the imagination. The publication of these cases put an end to the virtues of the metallic tractors in England.

Since the death of Mesmer, however, animal magnetism has had directed towards it a great amount of attention, and has been investigated by physiologists of eminence, and used as a curative agent by many medical men.

One of the first publications in this country on this subject was by Mr. Richard Chenevix, a Fellow of the Royal Society, who published a series of papers in the 'London Medical and Physical Journal' for 1829, entitled 'On Mesmerism, improperly denominated Animal Magnetism.' He performed numerous experiments, which were witnessed by many medical men, and amongst others by Dr. Elliotson. In 1836 Mr. Colquhoun published a work on animal magnetism, entitled 'Isis Revelata,' which attracted considerable attention to the subject, and contained as an appendix a translation of a report of a second French commission appointed to investigate this subject in 1831. This was followed by the arrival of Baron Dupotet in London, who performed many experiments, some of which were witnessed by Dr. Elliotson, who immediately undertook the further investigation of the subject. The result of the experiments of Dr. Elliotson, which were published in the 'Lancet,' produced a great sensation, and phenomena which had hitherto been regarded as impossible were constantly produced. Communications were also made at this time to various medical journals of remarkable cases, and among others were some from Mr. Herbert Mayo, then professor of physiology at King's College, London. In 1840 a work was published by the Rev. Chauncy Hare Townshend, entitled 'Tracts on Mesmerism, with reasons for a dispassionate inquiry into it.' This work contained many cases and facts with regard to the phenomena of animal magnetism. In 1841 M. La Fontaine, a Frenchman, visited England, and commenced giving public lectures on mesmerism and exhibitions of its phenomena. Whilst in Manchester he attracted the attention of the late Mr. Braid, a surgeon residing there, who, having repeated and modified variously the original experiments of the mesmerisers, published a work on the subject in 1843, entitled 'Neurypnology, or the Rationale of the Nervous Sleep.' Since this time various public lecturers have appeared, and have created a general interest on the subject. A great impulse was given to it by the publication of a series of letters in the 'Athenæum' from Miss Martineau, who attributed her cure from a long-standing ailment to the influence of animal magnetism. Subsequently to this, the subject was taken up in Edinburgh, and found a scientific advocate and exponent in the late Dr. Gregory, professor of chemistry in the University of Edinburgh.

The phenomena presented by persons under the influence of animal magnetism are various, as well as the modes by which the phenomena are produced. Mesmer and his followers on the Continent, and most of those who have practised mesmerism in this country, have produced its effects by placing themselves near to the individual to be mesmerised, and making downward passes with their hands over their bodies without touching them, but looking at them at the same time intently in the face. This is found to affect the individual in a space of time varying from two or three minutes to half an hour. All persons are not however susceptible of the influence, and if an effect is not produced in the course of half an hour, the effort is abandoned. Mr. Braid however, in the course of his inquiries, found that a second individual was not necessary to the successful development of mesmeric phenomena, and that by causing a person to sit still, and simply directing his attention, by means of the eyesight, to some particular object, as a lancet-case or a cork, all the effects of the passes and intense looking of the operator could be produced. This induced him to give another name, Hypnotism, to the state in which persons are thus placed.

The effects of the passes or fixed attention on persons of nervous susceptibility are various. Writers on animal magnetism distinguish many stages. The following classification is by Kluge, a German writer on the subject, and gives a tolerably correct estimate of the effects which have been observed in mesmerised individuals:—

First degree:—Called *waking*, presents no very remarkable phenomena. The intellect and the senses still retain their usual powers and susceptibility.

Second degree:—Half-sleep, or imperfect crisis. Most of the senses still remain in a state of activity, that of vision only being impaired, the eye withdrawing itself from the power of the will.

Third degree:—The magnetic or mesmeric sleep. The organs of the senses refuse to perform their respective functions, and the patient is in an unconscious state.

Fourth degree:—The perfect crisis, or simple somnambulism. In this stage the patient is said to "wake within himself," and his consciousness returns. He is in a state which can neither be called sleeping nor waking, but which appears to be something between the two.

Fifth degree:—Lucidity, or lucid vision. This is called in France, and mostly in this country *Clairvoyance*; in Germany, *Hellschen*. In this state the patient is said to obtain a clear knowledge of his own internal mental and bodily state, is enabled to calculate with accuracy the phenomena of disease which will naturally and inevitably occur, and to determine what are their most appropriate and effectual

remedies. He is also said to possess the same faculty of internal inspection with regard to other persons who have been placed in mesmeric connection (*en rapport*) with him.

Sixth degree:—Universal lucidity; in German, *Allgemeine Klarheit*. In this state the lucid vision becomes greatly increased, and extends to objects whether near or at a distance.

Such are the states of the system recognised by mesmerists, and works on the subject abound with cases illustrative of each of these six degrees. However, there are many who practise mesmerism who are sceptical with regard to the real existence of the two last degrees, although such cases are recorded by the best authorities on animal magnetism.

One of the most singular statements with regard to mesmerism is its application to phrenology. It is asserted that persons in the sleep-waking state, when that region of the head is touched or pointed at by the mesmeriser which is over the seat of the supposed phrenological organs in the brain, will exhibit the mental emotions and states which are peculiar to the exercise of these organs. Thus when the organ of language is touched, the patient talks; when wit, he laughs; when benevolence, he is kind, and so forth. Such cases are attested by Dr. Elliotson, Mr. Braid, Mr. James Simpson, and others.

The mesmeric state has been applied mostly to the cure of disease, for which purpose it was used by Mesmer when it first attracted public attention. It has also been used for the purpose of producing sleep during surgical operations, as well as a means of divination for the purpose of ascertaining past and future events. A case of this kind was related by Miss Martineau, in which one of her attendants was asserted to be able in the mesmeric condition to predict future events. The class of diseases which have been cured by its means are those which are known to medical men as functional nervous diseases. Various nervous diseases, such as paralysis, epilepsy, &c., come on from changes in the structure of various organs, but these are not susceptible of benefit from the mesmeric state. It is in those cases where no structural lesion can be supposed to exist, and which often yield to sudden changes of the mind from various causes of excitement, and which frequently cease without obvious cause, that the disease has yielded to this remedy.

Many theories have been propounded in order to embrace the facts of animal magnetism. Mesmer and his immediate followers attributed them to the action of a subtle fluid in the bodies of animals, which enabled them to exercise an influence on each other at a distance, just as a magnet affects iron; hence he called it animal magnetism. This hypothesis of a nervous fluid susceptible of being influenced and producing an influence more or less modified, was adopted by most writers on mesmerism till the appearance of Mr. Braid's experiments. The mesmeric state having been produced by Mr. Braid without any influence from a second person, he accounted for the phenomena by supposing that there was "a derangement of the cerebro-spinal centres and of the circulatory and respiratory and muscular systems, induced by a fixed state, absolute repose of body, fixed attention, and suppressed respiration concomitant with that fixity of attention." He further added, that in all cases he believed "that the whole depended on the physical and psychical condition of the patient, arising from the causes referred to, and not at all on the volition or passes of the operator throwing out a magnetic fluid or exciting into activity some mystical universal fluid or medium."

Whilst there can be little doubt with regard to many of the facts recorded on this subject, they have been so remarkably misrepresented through the feelings of those who have observed and narrated them, that men of science, disgusted with the imposture of some and the credulity of others, have generally shunned its investigation, and turned a deaf ear to what they consider the pretensions of its professors. There have been recorded several instances in which mesmeric cases have been tested by unprejudiced observers, and which have led to the conclusion that in these particular cases either imposition was practised or a false conclusion had been drawn from the facts. In the case of two girls put to the test by Mr. Wakley, editor of the 'Lancet,' and recorded in that periodical for September 1, 1838, there was strong reason to believe that many of the phenomena attributed to animal magnetism were assumed at the volition of the patient. Another instance is recorded by Sir John Forbes, in the same journal for August 3, 1844, in which he tested the powers of *clairvoyance* of a French youth named Alexis. In these experiments, which were conducted before many observers, the youth entirely failed to give evidence of any extraordinary mental powers during the mesmeric state.

A more scientific aspect was given to the whole of the phenomena of animal magnetism by M. Reichenbach, a distinguished German chemist, who imagined he had discovered a new force in nature, which he called Od force, or Odyle. This he regarded as a peculiar force in nature, whose presence could only be detected by persons of a highly susceptible nature, and all his experiments upon the subject were performed through the agency of such individuals. He applied his conclusions to the explanation of the phenomena of animal magnetism, but the circumstance of all his experiments having been performed through the medium of others, and those confessedly in a morbid state, has led to the very general rejection of his theory.

Another form which the public exhibition of animal magnetism has

assumed is that which is called "electro-biology." In the public performances of lecturers on this subject, persons are made to gaze for a certain length of time on a piece of money which is placed in their hands. In susceptible individuals this produces a kind of cataleptic sleep, from which they pass to a sleep-waking state. It is in this condition they exhibit all the phenomena of the mesmeric state. They become the victims of every suggestion made to them by the operator. If he tells them they are drunk, they stagger; if he says a glass of water is sweet, bitter, acid, or strong, they appear to believe it. In this state, also, they are capable of exerting an amount of muscular power of which they are utterly incapable whilst in their natural state. The mode of producing this sleep is nothing more than that which had been discovered by Mr. Braid, and the term electro-biology was only adopted to awaken attention to an old subject.

Although not essentially connected with mesmerism, from the absence of the characteristic sleep, yet having a relation to mesmerism in the mental states of those who are operated upon, we may here refer to table-turning, table-talking, spirit-rapping, and magnetometry.

The process of table-turning consists in the moving a table round, as the result of several persons joining their hands and resting them upon the table. They then resolve that the table shall move in one direction, and without any conscious effort on their part, the table moves. Professor Faraday showed by means of an ingenious instrument, that muscular force was exerted by the individuals surrounding the table, and that, when it was all made to tell in one direction the table moved in that direction, but if no force was exerted, or the force was exerted in different directions, the table did not move. In this case it was clearly shown that the persons operating were under the influence of a suggestion which, without Professor Faraday's instrument, they could hardly have suspected.

An instrument called a magnetometer was invented, which was supposed to indicate delicate magnetic states of the system. It consisted merely of a piece of sealing-wax, or wood, suspended on a string of silk. A variety of curious effects were said to be arrived at by this instrument. It moved in one direction when held by males, and another when held by females. It was influenced by persons holding different kinds of metals in their hands, and so on. The whole of this subject, however, was exploded when it was found that no definite effects were produced when persons were blindfolded. Here, again, the operators were the victims of their suggestions. They exercised their volition unconsciously, and attributed it to the existence of a mysterious force. This explanation serves to explain the further absurdities of table-talking and spirit-rapping. In the former the stopping of the turning-table when a question was asked, was certainly the result of the suggestion in the minds of those who were turning the table, and thus answers were got to all kinds of questions.

In spirit-rapping there appears to be more than mere self-delusion. In this case a person called a medium undertakes to communicate with spirits. The presence of the spirit is indicated by raps. These raps are undoubtedly performed by the medium, whilst the answers given to questions put by deluded persons, are dependent on the medium shrewdly taking advantage of their being under the influence of their own suggestions.

With regard to the mesmeric sleep, there can be no doubt that it is a real phenomenon, as well as the sleep-waking condition. It is, however, when persons are in this condition that they become, as it were, the slaves of suggestion. It is thus that the electro-biologist plays upon them at his will, and it is in this state that they become clairvoyant and universally lucid under the same law of suggestion.

The known fact of the great increase of force that takes place in normal conditions of the system when the whole attention is concentrated on an idea, serves to explain the feats of strength performed by persons in the sleep-waking state. The whole of this curious subject has been ably discussed by Dr. Carpenter in an article in the 'Quarterly Review.'

Although so many of the phenomena of mesmerism admit now of a rational explanation, it is still practised as a mystery, and large portions of the public give credence to the most marvellous assertions of those who practise it. In many of the cases exhibited before the public there is really no sleep-waking at all, and the persons who exhibit clairvoyance, and a power of reading thoughts without language, and books without eyes, are clever conjurors, who are perfectly awake, and exhibit none of the genuine symptoms of those psychological states which have excited so much interest in the minds of an uneducated public. [SOMNAMBULISM.]

MESOLABIUM, an old name for any geometrical construction or proportion for finding two mean proportionals between two given lines.

MESOXALIC ACID ($C_6O_8, 2HO$). When a saturated solution of alloxanate of baryta or strontia is heated to ebullition, a precipitate is obtained which consists of a mixture of mesoxalate, alloxanate, and carbonate of the base employed. On evaporating the barytic solution crystalline crusts are formed composed of urea and mesoxalate of baryta. When these are digested in alcohol the urea is dissolved, and the mesoxalate of baryta is unacted upon. If a solution of alloxan is gradually added to a boiling one of acetate of lead, a heavy granular precipitate of mesoxalate of lead is formed, and there remains in the acid liquor merely the excess of acetate of lead and pure urea. The

mesoxalic acid is obtained by treating the mesoxalate of lead or baryta with dilute sulphuric acid.

The properties of the solution thus obtained are, that it is very acid, reddens vegetable colours, crystallises, and produces, when saturated with ammonia, as alloxanic acid does, white precipitates in the salts of lead, lime, baryta, and strontia. These precipitates are soluble in acids and in a large quantity of water. A solution of mesoxalic acid may be boiled and evaporated without decomposing.

The distinguishing character of this acid is the mode in which it acts on the salts of silver. When a salt of silver is added to mesoxalate of ammonia, a yellow precipitate is formed, which becomes black, and is reduced with effervescence when the mixture is gently heated.

MESSENGER. [BANKRUPT.]

MESSENGERS AT ARMS are the officers who execute the writs issuing from the superior courts in Scotland. The duty of executing these appears to have rested with the Lyon King at Arms, aided by the heralds or other assistants. To this day the court of the Lord Lyon has authority to admit to the office of messenger at arms, and to dismiss a messenger for misconduct. Each messenger must find security for the proper performance of his official duties. Messengers require to perform their functions with great precision, as they are not only amenable to questions regarding the liberty of the subject, but have often to perform acts, on the legal accuracy of which the title to landed property may afterwards depend.

MESSENGERS, KING'S, or QUEEN'S, certain officers employed under the secretaries of state, who are kept in readiness to carry despatches both at home and abroad. They are not now employed so often as formerly in serving the secretaries' warrants for the apprehension of persons for high-treason or other grave offences against the state. Formerly too it was not unusual for them to keep the prisoners they apprehended at their own houses. A remarkable instance of this practice is detailed in the 'Post-Boy' newspaper of 1713. "London, Jan. 10.—Yesterday morning the Morocco ambassador was taken into the custody of one of her majesty's messengers, by way of reprisal for his master's ordering and committing to slavery several of her majesty's subjects." In the same paper, July 14, 1713, we read, "The emperor of Morocco having released those of her majesty's subjects that had been carried into slavery Don Bentura de Zari, his ambassador, who was in custody of Mr. Chapman, the messenger, by way of reprisal, was on Saturday last set at liberty." So that his excellency must have passed six months in the messenger's custody.

MESSIAH (מָשִׁיחַ) is a Hebrew word, of the same signification as the Greek *Χριστός* (Christ), *anointed*. In the Old Testament the word is repeatedly applied to persons who were consecrated to the service of God in some sacred office. Thus the Jewish priests, prophets, and kings are called *anointed* (Messiah), or *the anointed of God*. From this general meaning the word has passed into a particular use, referring to the illustrious personage whom the ancient Jews expected, and whom their descendants still expect, to confer some signal blessings on their nation and the world. The word is found in this sense twice in the Old Testament, in Psalm ii. 2, and in Daniel, ix. 25, 26.

The expectation of the Messiah, first excited by the promise given to Eve after the fall of man (Genesis, iii. 15), may be traced from the exclamation of Eve at the birth of Cain, "I have gotten a man from Jehovah," or "a man Jehovah" (Genesis, iv. 1), down through the patriarchal history, the Mosaic law, and the whole series of the Jewish prophets; and it is very generally admitted that remnants of the early belief upon this subject are plainly seen in the religion and traditions of nearly all heathen nations. For information on these traditions, see Dr. J. P. Smith's 'Scripture Testimony to the Messiah,' book ii., c. 2; and Bp. Horsley's 'Dissertation on the Prophecies of the Messiah, dispersed among the Heathen.' See also Hengstenberg's 'Christologie des Alten Testaments.'

The expectations of the Messiah among the Jews in the period between the close of the Old Testament and the birth of Christ, as indicated by the Targums, the Apocrypha, the Book of Enoch, and the writings of Philo and Josephus, were confused and often inconsistent. From Josephus we learn nothing on the subject, a fact sufficiently accounted for by his own temporising disposition and the circumstances in which he was placed.

At the time of Christ's advent various expectations respecting the Messiah prevailed among the Jews. It is sufficiently evident from the New Testament, that, while some looked for a human prince who was to deliver them from the Roman yoke and exalt them to national supremacy, others expected a divine teacher who was to confer spiritual blessings not only upon them but also on the Gentiles. (Bertholdt's 'Christologia Judaeorum Jesu Apostolorumque Aetate,' and Kuinoel's 'Comment. in Lib. Hist. N. T., Proleg. ad Johan., § 7.) The opinion of the Samaritans, recorded in John, iv. 42, that the Messiah would be a religious teacher and "the Saviour of the world," is worthy of special attention, because the Samaritans received no part of the Scriptures but the Pentateuch, and were cut off from all intercourse with the Jews by national hatred.

It is the belief of all Christians that Jesus Christ is the Messiah predicted in the Old Testament. The evidence of this fact is contained

in the New Testament, especially in the four gospels, from which it appears that his lineal descent, the place, time, and other circumstances of his birth, the constitution of his person, the history of his life and death, the miracles he performed, and the doctrines he taught, all agree to the minutest particular with the prophecies respecting the Messiah.

The Jews, having rejected the claims of Jesus Christ, are still looking for the Messiah, whom they almost universally expect to be a mere man and to confer on them only temporal blessings. Most of the Rabbinical writers of the middle ages speak of two Messiahs: one, the son of David, the conquering monarch; the other, the suffering Messiah, the son of Joseph, who is to fall in battle, fighting for his countrymen against Gog and Magog, and in this sense to die for them. This opinion may be traced up to the 6th century, and perhaps higher. In these Rabbinical writings, especially in the book 'Zohar,' there are scattered valuable fragments of the more ancient belief of the Jewish people on this subject. (Schöttgenii, 'Horæ Hebraicæ et Talmudicæ,' and Lightfoot's 'Works.')

In different ages there have appeared numerous "false Messiahs" (Matt., xxiv. 24). Of these ecclesiastical historians reckon twenty-four, for an account of whom the reader is referred to Johannes à Lent's 'History of False Messiahs.'

MET; META. Prefixes used in chemical nomenclature, to designate compounds closely related to the bodies before the names of which they are placed. Such bodies will generally be found described under the names *minus* the prefix; thus *metanaphthalin* will be noticed under *naphthalin*.

METACENTRE is a point in a floating body, the position of which, relative to that of the centre of gravity, determines the conditions for the stability or instability of the equilibrium of that body. The equilibrium is *stable*, if, when the body receives a slight disturbance from its position, it tends, by the combined action of its own weight and the pressure of the fluid in which it is partially immersed, to re-adjust itself in that position after some oscillations; and the equilibrium is *unstable* if a slight disturbance will cause the body to overset and acquire a different position, which will then necessarily be one of stable equilibrium.

The surface of a heavy fluid at rest is a horizontal plane; the portion of this plane which we may imagine to be within the floating body is called the *plane of floatation*.

When a body floating on a fluid is in equilibrium, the weight of the body applied downwards at its centre of gravity must be equal and exactly opposite to the pressure of the fluid, or, which is the same, to a force equal to the weight of the displaced fluid, applied upwards at the centre of gravity of this portion of the fluid; hence in this position the right line joining these two centres is vertical, and is called the *line of support*.

When the body is slightly disturbed from this position, the plane of floatation evidently alters its position in the floating body; the centre of gravity of the part immersed also changes, and the *thrust* of the fluid will in general no longer pass through the centre of gravity of the whole body. The magnitude of this force will however undergo but a very small change, and the body is now subjected to the action of two forces which are equal and contrary, but no longer directly opposite.

The figure and density of a body may however possibly be such that the thrust of the fluid may, after the disturbance, continue to pass through the centre of gravity of the body. The equilibrium is then said to be *indifferent*, inasmuch as the disturbance communicated only produces a new position of equilibrium. This happens when a body floats in a fluid of equal density with itself, and in other cases, as in a floating sphere. We may observe that if the disturbance of the equilibrium consisted merely of an elevation or depression of the centre of gravity, small vertical oscillations would be the consequence: the disturbance considered here is supposed such as to tend to turn the body *round* its centre of gravity, or to make the original line of support deviate in a vertical plane through a very small angle; this line is called the *axis* passing through the centre of gravity.

When the position of the body is thus disturbed, if the line of thrust

when produced upwards meets the above-named axis, the point of intersection is called the *metacentre*. The consequent motion of the body will then be the same as if the centre of gravity were fixed, and

the thrust applied vertically at the metacentre; hence if the metacentre be *above* the centre of gravity, the thrust tends to re-adjust the axis, and the equilibrium is stable; if *below*, that force tends to carry the axis farther from its original place, and the equilibrium is unstable: if the two centres coincide, the equilibrium is indifferent. We give an example:—

Fig. 1. ABCD is a vertical square section passing through G, the centre of gravity of a rectangular beam floating on a fluid of twice its specific gravity, this section being at right angles to the faces of the beam; therefore $GH = \frac{1}{2} AB$; and if $gH = \frac{1}{4} AB$, g is the centre of gravity of the fluid displaced, Gg is the line of support, and EF the plane of floatation.

Fig. 2.

Fig. 2 represents the same body turned round its centre of gravity through a small angle FGf or θ . Let $GF = 1$; we must find g' , the centre of gravity of $efCB$, and draw $g'o$ vertical or perpendicular to ef , cutting the axis GH in o the metacentre. Let m, n , be the centres of gravity of the portions EGe , FGf , and h that of the portion $egfCB$, then $hg:gm::$ solid EGe : solid $egfCB$; and $hg':g'n::$ solid FGf : solid $egfCB$; but the solids EGe , FGf , are equal: hence $hg:gm::hg':g'n$, therefore gg' is parallel to mn , or nearly horizontal, and $=mn$, $\frac{\text{solid } EGe}{\text{solid } egfCB}$ nearly. Now $mn = 2Gm = \frac{4}{3}$, and solid $EGe = \frac{1}{2} \theta \times \text{length}$, solid $egfCB = 2 \times \text{length}$; therefore $gg' = \frac{4}{3} \times \frac{1}{2} \times \theta = \frac{2}{3} \theta$; but $\angle gog' = \theta$; therefore $go = \frac{1}{3}$, or $GO = \frac{GH}{6}$: hence the equilibrium is unstable. If the equilibrium were stable, the times of the oscillations would be found by supposing the thrust applied at o , the point G remaining fixed.

METACETAMINE. [PROPYLAMINE.]

METACETIC ACID. [PROPIONIC ACID.]

METACETONE ($C_3H_6O_2$). When a mixture of 1 part of sugar and 8 parts of lime is submitted to distillation, the temperature, after reaching 284° Fahr., rapidly rises, and a very small quantity of combustible gas is liberated, accompanied with a liquor which is a mixture of acetone and metacetone. When water is added the metacetone separates, which is to be rectified, the last portions of the product being preserved.

Metacetone is a colourless liquid of an agreeable odour. It boils at about 153° Fahr.; does not mix with water, but combines with alcohol and ether. It is not improbable that metacetone is identical with propione, a body which stands in the same relation to propionic acid as acetone does to acetic acid.

METACETONIC ACID. [PROPIONIC ACID.]

METACETONITRYL. [PROPYL, Cyanide of.]

METACINNAMEIN. A modification of Styracin. [STYRACIN.]

METAFURFUROL. A very oxidisable oil accompanying furfurol.

METAGALLIC ACID ($C_{24}H_8O_8$); *Gallulmic Acid*; is prepared by the partial decomposition of gallic acid by quickly heating it up to about 480° Fahr. Carbonic acid and water are formed and separated, and a black, shining, tasteless compound is left, which is not dissolved by water, but is easily taken up by the alkalies ammonia, potash, and soda in solution. It also decomposes the solutions of the alkaline carbonates, expelling the carbonic acid. Metagallate of potash gives insoluble precipitates with the salts of baryta and strontia, and also with many metallic salts. [GALLIC ACID.]

METALDEHYDE. [OTHYL, HYDRIDE OF.]

METALLURGY is the art of separating metals from their ores. The processes vary for every metal, and are described under each.

METALS. The great characteristic of these well known substances is their lustrous appearance; it is indeed so constant an accompaniment of them as to afford, under the name of *metallic lustre*, a standard of description for the appearance of other bodies.

Metals, in the common acceptance of the term, are either compound or simple. Brass, bronze, britannia metal, &c., are examples of compound metals; that is, they are composed of two or more simple metals. Compound metals are, however, always distinguished as ALLOYS, and hence the word metal is correctly, though not invariably, applied only to the simple or elemental metals.

The metals or metallic elements are considerably greater in number than the non-metallic elementary bodies, or metalloids. Including one or two concerning whose metallic character there is a little doubt, the whole number is about forty-nine. Very few of them occur naturally in the free or uncombined state, being generally associated with non-metallic elements, constituting *ores*. Some of them are obtained with such difficulty that they are very rarely met with, existing only in the cabinets of the curious, or perhaps exclusively met with in the laboratories of the chemists who succeeded in isolating them. Several of them, however, such as gold, silver, copper, iron, lead, tin, and mercury, have been known from the most remote ages, and nearly all the rest are well known to chemists.

The physical characters of the metals, including colour, relative lustre, ductility, malleability, tenacity, relative brittleness, hardness, elasticity, sonorousness, structure, power of conducting heat and electricity, melting point, and volatility, have already been described under METALS, in the NATURAL HISTORY DIVISION of this Cyclopædia. Their condition and distribution in nature is also there dwelt upon, and the action of metalloids upon them cursorily noticed. The methods of separating them from each other have been given in the present division of the work, under CHEMICAL ANALYSIS; and it now, therefore, only remains to detail the various methods of classification that convenience or analogy has induced chemists and physicists to adopt.

The following is a useful descriptive method of classification, and is frequently employed in works on chemistry.

1.—Metals of the alkalis:—

Potassium	Sodium	Lithium.
-----------	--------	----------

2.—Metals of the alkaline earths:—

Barium	Strontium	Calcium	Magnesium
--------	-----------	---------	-----------

3.—Metals of the earths:—

Aluminium	Terbium	Lanthanum
Glucinum	Zirconium	Didymium
Yttrium	Thorium	
Erbium	Cerium	

4.—Oxidable metals, whose oxides form powerful bases:—

Manganese	Cobalt	Bismuth
Iron	Copper	Lead
Chromium	Zinc	Uranium
Nickel	Cadmium	

5.—Oxidable metals, whose oxides form weak bases or acids:—

Vanadium	Pelopium?	Antimony
Tungsten	Ilmenium?	Arsenic
Molybdenum	Titanium	Tellurium
Tantalum	Tin	Osmium
Niobium		

6.—Metals whose oxides are reduced by heat. Noble metals:—

Gold	Platinum	Ruthenium
Mercury	Palladium	Rhodium
Silver	Iridium	

Analytical Classification of the Metals.

Group I.

Potassium	Sodium	Lithium
-----------	--------	---------

Group II.

Barium	Strontium	Calcium	Magnesium
--------	-----------	---------	-----------

Group III.

Aluminium	Yttrium	Cerium
Chromium	Zirconium	Didymium
Glucinum	Erbium	Lanthanum
Thorium	Terbium	

Group IV.

Iron	Cobalt	Zinc
Manganese	Nickel	Uranium

Group V.

Gold	Iridium	Arsenic
Platinum	Tin	Antimony
		Molybdenum

Group VI.

Lead	Cadmium	Osmium
Silver	Copper	Palladium
Mercury	Bismuth	Rhodium
		Ruthenium

The following arrangement, founded upon the relative power of the metals to decompose water and the action of heat upon their oxides, is known as

Thénard's Classification of the Metals.

CLASS 1.—Metals which decompose water with brisk effervescence at 32° Fahr.:—

Potassium	Lithium	Strontium
Sodium	Barium	Calcium

CLASS 2.—Metals which do not decompose water under 212° , but far below a red heat :—

Aluminium	Yttrium	Cerium
Glucinum	Zirconium	Manganese
Thorium	Lanthanum	Magnesium

CLASS 3.—Metals which do not decompose water except at a red heat, or at common temperatures in contact with strong acids :—

Iron	Zinc	Chromium
Nickel	Cadmium	Vanadium
Cobalt	Tin	

CLASS 4.—Metals which decompose water at a red heat, but not at common temperatures, even in contact with strong acids :—

Tungsten	Tantalum	Antimony
Molybdenum	Titanium	Tellurium
Osmium	Arsenic	Uranium

CLASS 5.—Metals which do not decompose water even at a red heat, and whose oxides are not reduced by heat alone :—

Copper	Lead	Bismuth
--------	------	---------

CLASS 6.—Metals which do not decompose water under any circumstances, but whose oxides are reduced by heat :—

Silver	Gold	Platinum
Mercury	Palladium	Rhodium
		Iridium

The special characters of the metals; their farther relation to, and action upon, one another; the action of metalloids, acids, &c., upon them individually; and the formation, properties, use, &c., of their compounds, will be found described under their respective names, with the exception of iron, which we shall now proceed to describe.

Iron (Fe). In combination with other bodies, iron is perhaps more widely diffused than any of the metals. It is found in the ashes of nearly all plants, is a constant constituent of the blood of the vertebrate animals, and although only a few of its ores are economically made use of, they are more numerous than those of any other of the heavy metals. [IRON, in NAT. HIST. DIV.] The range of affinities of iron is so great that it is very rarely met with in the uncombined state, and it is only with considerable difficulty that it can be artificially obtained in an absolutely pure condition. The process recommended by Berzelius for preparing chemically pure iron consists in heating filings of the best bar iron with pure oxide of iron under a layer of powdered green glass in a Hessian crucible: the whole being subjected to the highest temperature of a smith's forge, the filings are deprived of their carbon and silicon by the oxide, and fusing together collect at the bottom of the crucible in a button possessing silver-like lustre and whiteness. Iron thus prepared has a specific gravity of 7.8439, and is very tough and much softer than the ordinary metal. Another method of procuring perfectly pure iron is by passing a current of hydrogen gas over pure peroxide of iron, heated carefully to redness: if the temperature is too low the resulting product inflames spontaneously on coming in contact with the air, but when prepared at a higher temperature may be kept unaltered; in this state it is sometimes used in medicine, under the name of *Quevennes iron*, *Fer reduct*, or *Pulvis ferri*.

Pig, cast, malleable, and rolled iron are the ordinary states of the metal met with in commerce; their manufacture and properties have already been described. [IRON MANUFACTURE AND TRADE] In one or more of these conditions iron has been known from the most remote period. Cutting instruments made of this metal are mentioned in the books of Moses. The method of reducing and forging iron is described in Homer and Hesiod, and Pliny's 'Natural History' contains a long article on the subject. The alchemists considered it to be a compound of gold and the hypothetical body *acrimony*, and symbolised it therefore by the sign ζ ; they gave it the name of *Mars*, probably because weapons made of it were used in the service of the god of war.

Iron has a white or grayish white colour. When tolerably pure, as in bar-iron, it is very difficult of fusion, but at a white heat possesses the valuable property of welding; that is, two pieces brought into contact at that temperature, and well pressed together by hammering, unite as perfectly as if they had been joined by melting. The heat of the oxyhydrogen blowpipe or of the voltaic arc, however, is sufficient to even volatilise iron. Iron can be beaten out into tolerably thin sheets, but is not nearly so malleable as gold or silver. It is very ductile, being capable of being drawn into thinner wire than that of any other metal. In tenacity also it is unsurpassed, a wire of one thirty-sixth of an inch in diameter sustaining a weight of sixty pounds before breaking. Iron readily conducts heat and electricity, but is inferior in these respects to some other metals. It is attracted by the magnet, and may itself be rendered permanently magnetic; the latter property is destroyed on heating the metal to redness, but is recovered again on cooling.

Under the influence of air and moisture iron rapidly attracts oxygen, or *rusts*, especially after the first spot has been produced. The exact action that goes on is not very well made out; it appears probable that the peroxide first formed is reduced to the state of protoxide by the particles of the metal with which it is immediately in contact, the protoxide so produced absorbing oxygen from the air and being re-con-

ARTS AND SCI. DIV. VOL. V.

verted into peroxide; in short, that the peroxide of iron protoxidises the metal and that the air peroxidises the protoxide. The carbonic acid present in the air also plays an important part in the rusting of iron. This liability of iron to rust is perfectly prevented by keeping it dry; but the object is most commonly effected by constant removal of the surface of oxide by polishing powders, such as emery or brick-dust, or by enveloping the metal in a covering of plumbago, a mechanical process known in domestic life as *blackleading*.

Iron decomposes water at a red heat, hydrogen being evolved, and a black oxide of iron produced. Diluted sulphuric, hydrochloric, nitric, and other acids dissolve iron, with evolution of hydrogen or, in the case of nitric acid, of binoxide of nitrogen. Strong nitric acid, however, does not act upon iron, the metal remaining in what is termed the *passive condition*, a condition that seems to be intimately connected with the electrical relations of this metal.

Wrought iron, steel, and cast iron differ from each other chemically chiefly in the amount of carbon they contain. Thus wrought iron contains only from about 0.2 to 0.4 per cent.; steel, from 1.3 to 1.5; while cast-iron sometimes contains as much as 5.0 per cent. of carbon. From recent researches it appears that to the presence of a greater or smaller quantity of titanium is owing the value of iron used for making steel, and that titanium moreover confers other important properties on iron. Iron also sometimes contains silicon, sulphur, phosphorus, arsenic, and traces of other metals, such as aluminium, calcium, potassium, manganese, &c., but these deteriorate its quality.

The combining equivalent of iron is 28, and its symbol (Fe), (from *ferrum*, Lat.). It unites with other elements and compounds, chiefly in two proportions, forming respectively *protosalts* and *persalts*. In the former the constituents are equal in number; in the latter, two equivalents of iron are associated with three of the other body, and for that reason are sometimes called *sesquisalts*.

Iron and oxygen form three definite compounds :—

1. Protoxide of iron FeO
2. Peroxide of iron Fe₂O₃
3. Ferric acid FeO₃

A fourth is also sometimes described, it contains Fe₃O₄, and is termed the *black* or *magnetic oxide*, but it does not form salts, and may be viewed as a combination of one equivalent of protoxide with one of peroxide (FeO + Fe₂O₃ = Fe₃O₄). It is in fact formed by precipitating a solution of equivalent quantities of a proto and per-salt by an alkali. The natural form of this oxide is the well-known mineral *loadstone*, and is the valuable ore from which Swedish iron is smelted.

1. **Protoxide of iron (ferrous oxide) (FeO).** This body, though a very powerful base, and forming, with acids, a well-marked class of compounds called salts of protoxide of iron, is nevertheless not known in the separate state, so readily does it take up oxygen and form peroxide. In the hydrated state (FeO.HO) it is precipitated in white flocks on adding an alkali to a solution of a protosalt of iron. If care is not taken to exclude every trace of air from the liquid used in its preparation it is contaminated with more or less peroxide, and then falls down as a light green or blue precipitate. In contact with air it gradually becomes entirely converted into red peroxide.

2. **Peroxide of iron (sesquioxide or ferric oxide) (Fe₂O₃).** This oxide occurs native as *hematite*, *specular iron ore*, &c. [IRON, in NAT. HIST. DIV.] It is artificially prepared by heating the hydrate, or by igniting the protosulphate. Under the names of *colcothar*, *crocus of Mars*, *rouge*, &c., it is largely used as a pigment, and for polishing glass and jewellery. The *hydrated oxide* (Fe₂O₃ . x HO) is best prepared by precipitating a solution of the perchloride or persulphate with ammonia, well washing and gently heating. When first precipitated this hydrate is very flocculent and bulky, but contracts remarkably on drying. It has a dull red colour, not nearly so bright as the anhydrous oxide. It forms salts with acids, but is a weaker base than the protoxide.

Hydrated peroxide of iron is now largely used for the purification of coal-gas. [GAS-LIGHTING.]

3. **Ferric acid (FeO₃)** is not known in the free state. Combined with potash it is obtained on heating to bright redness peroxide of iron with four times its weight of nitrate of potash. It is very soluble in water, forming a dark violet solution. Other *ferrates* are produced by double decomposition; they are all uncrystallisable and very unstable, readily yielding up their oxygen, especially to organic matter.

Iron and sulphur combine in several proportions. The two most important sulphides are :—

1. Protosulphide of iron FeS
2. Bisulphide of iron FeS₂

1. **Protosulphide of iron (FeS)** is a bye-product in certain metallurgic operations with copper. It is of little value, being chiefly employed in chemical laboratories for the generation of sulphuretted hydrogen. For this purpose it is sometimes prepared by fusing together equivalent proportions of iron (filings) and sulphur, or better, by rubbing rolls of sulphur on a bar of iron heated to whiteness in a smith's forge, the liquid sulphide being allowed to flow down into cold water.

2. **Bisulphide of iron (FeS₂) (iron pyrites)** occurs native in beautiful brass-yellow crystalline masses. It is valueless as a source of metal,

Q Q

but under the name of *mundic* is extensively used as a source of sulphur in the manufacture of sulphuric acid. Some varieties of it decompose when exposed to air, being gradually converted into sulphate of iron. [ALUM.]

The *phosphides* of iron are unimportant.

Iron and chlorine form two compounds:—

1. Protochloride of iron FeCl
2. Perchloride of iron Fe₂Cl₃

1. *Protochloride of iron* in the anhydrous state (FeCl) is obtained on passing dry hydrochloric acid gas over iron filings heated to redness, hydrogen is evolved, and the salt sublimes in white micaceous scales. In the hydrated condition it may be prepared by dissolving iron in hydrochloric acid, and evaporating in vacuo; green crystals are then produced (FeCl + 4 Aq.), which must be preserved in an atmosphere of hydrogen or of carbonic acid.

Other metals may be coated with iron by boiling them in a solution of protochloride of iron containing chloride of ammonium and pieces of zinc.

2. *Perchloride of iron* (Fe₂Cl₃) (*sesquichloride*). Obtained in brown scales on passing excess of chlorine over iron heated to redness. It sublimes at a red heat, is soluble in alcohol or ether, and is very deliquescent. The *hydrated perchloride* is deposited in large red crystals on evaporating a solution of the hydrated peroxide in hydrochloric acid. They contain six equivalents of water of crystallisation. Solution of perchloride of iron has a great tendency to dissolve peroxide, and on evaporation the solution yields a confusedly crystalline mass of uncertain composition. The following is a convenient method of preparing a definite solution of perchloride of iron. Five parts of iron filings are dissolved in twenty parts of the common strong hydrochloric acid, the liquid filtered through asbestos, three additional parts of the acid then poured in, and the whole heated to ebullition; nitric acid is now gradually added till no more red fumes are evolved, when the iron will all be in the state of perchloride. If necessary, the solution may be evaporated to the crystallising point; if carefully prepared it will contain no free acid.

Solution of perchloride of iron mixed with alcohol forms the *tincture of sesquichloride of iron* used in medicine.

Iron and iodine,

Iron and bromine, and

Iron and fluorine form combinations corresponding to the two chlorides. The only one of importance is the

Protoiodide of iron (FeI). This salt is used in medicine, and is prepared by boiling iodine with excess of iron filings, or small nails, in water. On evaporation, the solution yields green crystals, containing FeI + 4Aq. These crystals fuse on the application of a moderate heat, give off their water of crystallisation, and on cooling solidify into a steel-grey crystalline mass. In manipulating with iodide of iron, contact of air should be avoided as much as possible, as an oxyiodide is very apt to form; the operations should also be conducted in iron vessels, and when in solution a piece of iron wire should be immersed in the liquid.

Protocarbonate of iron (FeO, CO₂) occurs native. It is from this ore that most of the English iron is obtained. [IRON, in NAT. HIST. DIV.] It also exists, dissolved by the aid of carbonic acid, in certain natural waters or chalybeate springs. It may be formed artificially by precipitating a protosalt of iron with an alkaline carbonate: at first it is white, but rapidly loses carbonic acid, absorbs oxygen from the air, becomes green, black, and finally red (peroxide of iron). This change may be considerably retarded by mixing it while moist with powdered white sugar, and rapidly drying over a water-bath; it then constitutes the *carbonate of iron with sugar* of the London Pharmacopœia.

Phosphates of iron are numerous, but ill defined. The principal are these:—

1. Phosphate of protoxide of iron.
2. Phosphate of peroxide of iron.
3. Pyrophosphate of peroxide of iron.

1. *Phosphate of protoxide of iron*, or *protophosphate of iron* (2FeO, HO, PO₅, or 3FeO, PO₅). This is obtained as a white precipitate on adding ordinary tribasic phosphate of soda to protosulphate of iron. It is insoluble in water, but soluble in solution of phosphoric acid, and the latter liquid, when mixed with sugar, constitutes the *syrup of phosphate* (or *superphosphate*) of iron used in medicine.

2. *Phosphate of peroxide of iron*, or *perphosphate of iron* (Fe₂O₃, PO₅ + 4Aq.), falls as a white precipitate on mixing solutions of a persalt of iron and ordinary tribasic phosphate of soda. Unlike the protophosphate, it does not absorb oxygen from the air, and, being of constant composition, is frequently used in quantitative analysis as a means of estimating phosphoric acid. It is insoluble in acetic acid, but soluble in solution of peracetate of iron.

3. *Pyrophosphate of peroxide of iron* (*pyrophosphate of iron*), (2Fe₂O₃, 3bPO₅ + 9Aq.), a white powder produced by double decomposition of a persalt of iron with dibasic phosphate (or pyrophosphate) of soda. It is insoluble in water or in dilute acids, but soluble in alkaline pyrophosphates or citrates, such solutions yielding, when evaporated to a syrup and spread over glass plates, beautiful transparent scales of yellowish-green or red colour. They are used in medicine under

various names, the *citro-ammoniacal-pyrophosphate of iron and soda* being one of them.

Sulphates of iron are two:—

1. Protosulphate of iron.
2. Persulphate of iron.

1. *Protosulphate of iron*. *Green vitriol*. *Copperas*. (FeO, SO₃ + 7Aq.) This salt is largely produced in the manufacture of ALUM. It is also formed in the process for precipitating copper from the solution of sulphate of copper obtained in certain metallurgical operations with that metal. Old scrap iron is used for this purpose, and, replacing the copper in solution, is obtained as sulphate of iron on evaporating the liquor. Sulphate of iron may be formed on the small scale by dissolving iron in dilute sulphuric acid. The following decomposition takes place:—

On evaporating the solution the salt crystallises out in beautiful bluish-green rhomboidal crystals. These, however, like all the protosalts of iron, must be exposed as little as possible to the air, for they quickly absorb oxygen, and a separation into basic and neutral persalts results, thus:—

Subsulphates of other composition are also frequently produced.

Protosulphate of iron is insoluble in alcohol, soluble in twice its weight of cold water, but much more so in hot water. When heated it loses six equivalents of its water of crystallisation, at a red heat is decomposed into sulphurous and sulphuric acids, which escape, while peroxide of iron (colcothar) remains. It is largely used in black DYEING and in the manufacture of writing INK.

2. *Persulphate of iron* (Fe₂O₃, 3SO₃). Five parts of crystals of protosulphate are dissolved in water, one part of sulphuric acid added, and nitric acid poured into the hot solution till no more black colour is produced. Abundance of nitrous vapours are evolved, and the yellow solution, on evaporation to dryness, yields a buff-coloured mass of persulphate of iron, having the above composition.

This salt occurs native. [IRON, *Coquimbite*, in NAT. HIST. DIV.]

Potassio-sulphate of iron (Fe₂O₃, 3SO₃ + KO, SO₃ + 24Aq.) is a double salt containing persulphate of iron and sulphate of potash. Corresponding salts with the other alkaline sulphates may also be formed. They all crystallise, and, being isomorphous with common alum, are frequently, though erroneously, called *iron alums*. They are formed by the spontaneous evaporation of mixed solutions of the salts, are to some extent used in medicine, but are liable to decompose.

The *iodate*, *bromate*, and *perchlorate* of iron are indefinite, unimportant salts.

Nitrates of iron.—The *protonitrate* (FeO, NO₃) is formed when cold nitric acid is saturated with protosulphide of iron: on evaporating the solution in vacuo, the salt crystallises out in pale green crystals containing seven atoms of water. The crystals are very deliquescent, and unstable. The *pernitrate* is produced when metallic iron is dissolved in strong nitric acid. It is very difficult to crystallise, the solution on evaporation depositing a basic salt. Solution of pernitrate of iron is used in dyeing.

Silicates of iron. Many of these occur native. [IRON, in NAT. HIST. DIV.]

Arsenites and arsenates of iron. In cases of poisoning by arsenic, the best antidote to administer is freshly precipitated peroxide of iron mixed with a little hydrate of magnesia. The efficiency of this antidote depends upon the formation of perarsenite of iron, which is an insoluble compound; that is, insoluble in water, but not altogether insoluble in the liquids of the stomach, which usually contain traces of hydrochloric, acetic, and lactic acids: the solution may, however, be prevented by mixing the oxide with magnesia, which neutralises those acids in a far more effectual manner than excess of peroxide of iron would do.

Acetates of iron. [ACETATE.]

Gallates and tannates of iron. [INK: *Writing Ink*.]

Citrates of iron. A double citrate of iron and ammonia is obtained when freshly precipitated protoxide of iron is dissolved in citric acid and excess of ammonia added. The compound does not crystallise; but when the solution is evaporated to the consistence of syrup and spread over glass plates it dries up and forms brilliant transparent scales of garnet-red colour.

Citrate of iron and quinine is a medicinal agent of some repute. It is prepared by dissolving together three parts of citrate of iron and one of citrate of quinine, and scaling as just described. The citrate of iron is made by saturating citric acid with moist peroxide of iron, evaporating and scaling; and the citrate of quinine by double decomposition of sulphate of quinine and citrate of soda.

Tartrate of iron. A double compound of tartrate of iron and potash, of somewhat similar physical properties to the last preparations, but

darker in colour, may be formed by dissolving moist, recently precipitated peroxide of iron in a hot solution of bitartrate of potash. This compound is also used in medicine.

Alloys of iron are numerous, but only two are important, namely, those with tin and with zinc. The former will be found described under TIN (*tin-plate*); the latter is produced when sheets of iron, cleaned as perfectly as if required for tin-plate, are dipped into a bath of melted zinc, on the surface of which is a stratum of sal ammoniac. The surface of the iron then becomes alloyed with zinc, and is thus preserved from oxidation by the air when employed in exposed situations. Moreover articles made of *galvanised iron*, as this zinc plate is commonly called, are easily soldered together, which is not the case with sheet-iron alone.

Tests for iron. Solutions of the *protosalts* yield greenish or bluish-white precipitates with the alkalis, or their carbonates; none with sulphuretted hydrogen; black with sulphide of ammonium; dark blue with red prussiate of potash; and light blue with the yellow prussiate of potash.

Solutions of the *persalts* give red-brown precipitates with the alkalis or their carbonates; are reduced to the state of protosalts by sulphuretted hydrogen, a light yellow precipitate of sulphur occurring at the same time; are precipitated black by sulphide of ammonium; dark blue by the yellow prussiate of potash, and not at all by the red prussiate of potash. Exceedingly small quantities of iron may also be detected in solution by the sulphocyanide of potassium, which gives a red liquid, and by tincture of galls which produces a black colour (ink).

In the *quantitative estimation of iron* the metal is always weighed in the form of peroxide. The definite state of the latter is ensured first by boiling the solution with nitric acid in order that the iron may be completely peroxidised, and second by precipitating with ammonia, because any trace of the salts of that alkali may be readily expelled by igniting the well washed precipitate. The resulting red oxide of iron is pure sesquioxide (Fe_2O_3), and contains, in one hundred parts, seventy of iron (Fe) and thirty of oxygen (O).

Ferrocyanogen (Fcy or $\text{Cfy} = \text{FeCy}_3$) is a bibasic radical which has not been isolated, but which is assumed to exist in certain familiar chemical compounds. With two equivalents of hydrogen it forms FERROCYANIC ACID (H_2Cfy), and with two of metal a class of salts called *ferrocyanides*, of which ferrocyanide of potassium (K_2Cfy) is a type.

Ferridcyanogen (Fedy or $\text{Cfdy} = \text{Fe}_2\text{Cy}_6$) is a similar radical, but tribasic. With three equivalents of hydrogen it forms FERRIDCYANIC ACID (H_3Fedy), and with three of metal, a class of salts called *ferridcyanides*, of which ferridcyanide of potassium (K_3Fedy) is the type.

Prussian blue is a variable mixture of the ferro- and ferrid-cyanides of iron. [BLUE: *prussian blue*.]

METAMARGARIC ACID. An acid of the same composition as margaric acid. Its existence has not been satisfactorily established. [MARGARIC ACID.]

METAMECONIC ACID. [MECONIC ACID.]

METAMERIC COMPOUNDS. [ISOMERISM.]

METAMERIDES. Chemical compounds which have the same combining proportion, but which differ in constitution and properties.

METAOLEIC ACID. [OLEIC ACID.]

METAPECTIC ACID. [PECTIC ACID.]

METAPHOR (*μεταφορά*, literally 'a transference'), a figure of speech which renders the subject of discourse striking, by the aid of expressions primarily referring to other objects. A common kind of metaphor is that called personification, where inanimate beings are represented as endowed with life, and even with feeling, reason, &c., as "the fields do laugh and sing,"—"stern winter." If this kind of metaphor spiritualises the corporeal, another kind, on the contrary, embodies the spiritual, as "the star of renown"—"the pinnacle of honour," and so on. A third kind is little else than a shortened simile, two objects in the same sphere being brought together, only on account of their resemblance. To this kind belong such expressions as "the silver moon"—"the golden sun," &c., where it will be seen at once that "silver" and "moon," gold" and "sun," are connected merely on account of their obvious similarity of colour and brightness. The origin of the first two kinds of metaphor is not so apparent, for though they likewise express a similarity, yet the similarity of a series of bodily objects to a series of objects merely of the mind, where there can of necessity be no sensible resemblance, is a subject for psychological investigation. The application of certain metaphors, in all languages and among all people, attracted the attention of Jean Paul Richter, who remarked that, "no nation called error, light, or truth, darkness." If we attend to the state of language, we shall find that a great part of the commonest discourse is composed of metaphors of the second kind, and that nearly all words expressing mental states, operations, and affections are in fact metaphorical. Thus, we say every day "a man of extended views"—"a man of good capacity, acute judgment," &c., where the words "extended," "views," "capacity," "acute," evidently belonged originally to material objects, but have been applied to things immaterial by metaphors. The circumstance that material objects are more apparent, that language seems primarily to have them for its sole objects, and that when a higher degree of reflection brings with it objects belonging to the mind

alone, nothing is left but to apply in a new sense the words already formed, is sufficient to explain the use of these metaphors generally. But still the fact that such and such bodily attributes are universally predicated of such and such spiritual objects alone, may still furnish matter for consideration to the curious in psychological speculation.

METAPHYSICS, a name originally applied to those books of Aristotle which followed his 'Physics,' and which his editors called 'the books after the Physics' (*μετὰ τὰ φυσικά*). In modern times the word has been variously applied, and seems to assume quite a distinct meaning as employed by different authors. With the Germans, metaphysics is a science purely speculative, which soars beyond the bounds of experience. The objects of this science are supersensual ideas, unattainable by experience, and the difficulty of defining the word lies in the circumstance that the very knowledge of the ideas sought requires some proficiency in the study. Hence to one altogether unacquainted with speculative philosophy it is almost impossible to explain the meaning of the word "metaphysics" as used in this sense. The very possibility of a science beyond experience has been denied by a great number of philosophers, and many works called metaphysical should rather be termed inquiries into the possibility of metaphysics. Thus Kant's celebrated work, the '*Kritik der reinen Vernunft*,' is a mere inquiry into the possibility of a theoretical science of things beyond experience, which terminates with a denial of such possibility; and hence some modern philosophers have considered Kant as no metaphysician, but as a critic of the mental faculties, whose labours were to be the precursors of a new system of speculation. On the other hand, a work like Spinoza's "Ethics" is purely metaphysical. He assumes the possibility of his science, and, proceeding from a number of axioms, speculates accordingly. Those who deny the possibility of metaphysics deny even the right to assume any axioms as applicable to a sphere beyond experience; and those who did assume them, as Spinoza, Leibnitz, and Wolf, were called by the Kantians dogmatists, in opposition to their own appellation of critics. The great point to be established prior to metaphysical speculation is the identity, or at least the necessary concurrence, of thought and being. This once established, speculative inquiry may proceed, as the results of logical investigation must in such a case, of course, concur with the nature of being itself; but the sceptics always deny the right of assuming such identity or concurrence, while on the other hand different theories have been adopted to prove them, such as those of harmony between body and spirit,—of the non-being of body altogether, except as an affection of spirit,—of an absolute identity between thought and being, &c. It may be as well to observe that the critical philosophy, which assumes nothing but the "I" or "ego," and the laws of thought (Fichte deducing even the latter from the axiom, "I am I"), has Descartes for its author, whose "Cogito, ergo sum," lies at the basis of most modern systems. [DESCARTES, in BIOG. DIV.]

In England, the word metaphysics is usually applied to denote the philosophy of mind, as distinguished from that of matter. This science treats of the association of ideas, memory, and various phenomena of mind; and as it consists merely in collecting facts and making inductions like any other experimental science, its possibility is no more questionable than that of chemistry or electricity. However, Locke's 'Essay on the Human Understanding,' as a denial of any source of knowledge other than experience, may be put at the side of Kant's 'Kritik,' as containing inquiries of similar nature, though the results be different; Berkeley's 'Idealism' may be compared with the "Wissenschaftslehre" of Fichte, and the Common-sense theory of Reid with the views of Jacobi. The philosophy of mind as an experimental science has been chiefly treated by the modern Scotch philosophers, among whom the late Sir W. Hamilton holds a high place.

METATARTARIC ACID. [TARTARIC ACID.]

METEMPSYCHOSIS (*μετεμψύχωσις*), derived from a Greek word signifying the passage or transmigration of souls, forms a part of the philosophical or religious belief of many nations. The Hindus believe that the souls of men pass after death into different bodies, either of men or animals, unless an individual has lived a most holy and religious life; in which case his soul is absorbed into the divine essence. "The soul passes from one state to another invested with a subtle frame consisting of elementary particles, the seed or rudiment of a grosser body. Departing from that which it occupied, it ascends to the moon, where, clothed with an aqueous form, it experiences the recompense of its works; and whence it returns to occupy a new body with resulting influence of its former deeds. But he who has attained the true knowledge of God does not pass through the same stages of retreat, but proceeds directly to reunion with the Supreme Being, with which he is identified, as a river at its confluence with the sea merges therein altogether. His vital faculties and the elements of which his body consists are absorbed completely and absolutely; both name and form cease; and he becomes immortal without parts or members."

('Extracts from the *Brahma-sūtras*, or Aphorisms on the Vedānta doctrine, by Bādarāyana,' translated by Mr. Colebrooke, in 'Trans. of the Roy. As. Soc.' vol. ii.)

The migration of souls from one body to another also formed, as is well known, a leading feature of the Pythagorean doctrine. This doctrine was also a part of the Egyptian religious system. The Egyptians, says Herodotus (ii. 123), are the first who believed in the

immortality of the soul. As soon as the body begins to decay, the soul passes from one animal to another; and when it has passed through the forms of all animals, terrestrial, aquatic, and winged, it again enters a human form. This period of transmigration is completed in 3000 years. Some of the Greeks, he adds, both in early times and more recently, have maintained this doctrine and claimed it as their own; and though he could mention names, he declines to do so.

METEOROLOGY, in its extended sense, embraces all physical causes which affect the state of the atmosphere or are affected by it. Hence it is connected with the phenomena of heat and cold, dew, rain, hail and snow, clouds, winds, auroræ boreales and australes, or polar lights, haloes, parhelia, &c. The sense in which Aristotle (*Μετεωρολογία*, i.) uses the term is still more extensive, comprehending, in addition to what are now called meteors, every affection (*πάθος*) common to the air and water, with the characters of the different parts of the earth, and their affections, as winds and earthquakes, and everything incident to such kinds of motion.

Our first inquiry shall be, what is the nature and what the probable extent of the terrestrial atmosphere? Essential as it is both to animal and vegetable life, to the distribution of heat, and to various modifications of light, the knowledge of its nature and composition is eminently useful. The air, though composed of several elastic fluids, obeys the same laws to which they are individually subject, namely, its elasticity and density at a given temperature are proportional to the pressure which it sustains, and for every degree of the centigrade thermometer under a given pressure it expands very nearly $\frac{1}{273}$ of its volume at the temperature zero. Hence if its density be represented by δ and its temperature by t (in centigrade degrees), its elastic force will be proportional to $(1 + \alpha t) \cdot \delta$ (where α represents the decimal .00375) as well as the pressure sustained. Lastly, the pressure is equal to the weight of a vertical column of atmosphere, having the portion pressed on as a base, and extending upwards to its extreme limit.

According to Dalton's views, the various gases constituting the air are not chemically combined by the law of definite proportions, but only mechanically mixed, co-existing in the same space, and producing by the sum of their independent pressures the elevation of the mercury in the barometric tube. In modern chemical physics, they are said to be mingled by the principle of DIFFUSION, which is the form in which Dalton's conception is now held.

We have seen that heat increases the elastic power of air, and hence the equilibrium of a mass of air unequally heated is constantly disturbed. The currents of warm and cold air change places, the cold air moving to the warm region, and thence, when warmed, repeating the course of the previous warm air. Thus the atmosphere is a great agent in tending to equalise the mean temperatures of climates in various latitudes. Besides, the aerial currents are vehicles for the transfer of clouds, for producing electrical discharges, for clearing away malaria, and are turned by the ingenuity of man to promote his industry and extend his knowledge of the globe which he inhabits.

The atmosphere, considered as a transparent medium, has also great effects on light by its refractive power, and the reflection of the aqueous masses it contains. Hence arises twilight, which mitigates the transition of day to night, and from the duration of which it is easy for the astronomer to compute that altitude of the atmosphere at which it ceases to act sensibly on light, either from its total absence or extreme tenuity. This altitude is from forty to fifty miles above the level of the sea. Again, by the refractive power of the atmosphere distant terrestrial objects are elevated to the view when the spherical curvature of the earth would otherwise have caused their concealment; various optical illusions, as the mirage, *fata morgana*, &c., are all easily explained from the same refractive power under peculiar circumstances of temperature. By this medium sound is conveyed and odours are, at least in part, disseminated; the clouds which float in it soften the direct glare of the solar beams, and its aqueous particles, fluid or frozen, produce the beautiful phenomena of haloes, rainbows, false suns, &c. Its greater specific gravity elevates the balloon, by means of which the nature of the upper strata of the air below the altitude of between four and five miles, may be ascertained, and the barometric elevation and temperature observed, which furnish data for calculating the physical limits of the atmosphere.

With regard to the extent of the atmosphere, we may consider it under two points of view: first, the extreme limits to which it is possible for it to extend, considered mathematically as a mass rotating round the terrestrial axis in the same time; secondly, the much narrower physical limits founded on its nature as an elastic fluid, and having regard to the great diminution of temperature at high altitudes.

Any particle of the revolving atmosphere is acted on by two forces, namely, gravity, which is directed nearly to the centre of the earth, and the centrifugal force produced by rotation, which is directed according to the line by which that point is orthographically projected on the earth's axis, and tends directly from that axis. The former force varies inversely as the square of the distance from the earth's centre; the latter, directly as its perpendicular distance from the earth's axis. At any point taken in the external surface of the atmosphere, the resultant arising from both forces must be normal to that surface, in order that its form may be permanent. At the terrestrial equator the ratio of these two forces is known; as we ascend in the atmosphere along an equatorial radius produced, gravity diminishes

and centrifugal force increases, both in this instance being directly opposite: hence it is easy to calculate the distance of a point in that radius where the two forces are exactly equal. Beyond that point the centrifugal force predominates, and no particle there situated could remain attached to our atmosphere, revolving with the earth both in its diurnal and orbital motions.

The above point therefore defines the extreme limit to which it is possible for our atmosphere to extend, and which is at a distance of about 30,000 miles from the centre, or 26,000 from the earth's equatorial surface, though it by no means follows that it must extend so far. Other data would be necessary to give the actual extent; for instance, the height of the barometer at the surface of the sea, and the law of the diminution of temperature in the upper strata of the air. The figure of the extreme surface can however be determined from these considerations, which is that of an oblate spheroid flattened at the poles, and in which the polar axis is to the equatorial in the ratio of 2 to 3.

As the phenomenon of twilight indicates an extreme degree of rarefaction in the atmosphere at an inconsiderable altitude above the earth's surface, we shall now consider some of the physical causes which demonstrate that the actual limits of that fluid are much more contracted than the extreme possible limits given above.

Representing by p , δ , and t respectively, the pressure, density, and temperature of the air at the surface of the earth, and by p' , δ' , and t' , like quantities for a portion of air at a certain elevation, it follows from

the general laws of gaseous bodies that $\frac{p'}{p} = \frac{(1 + \beta t') \delta'}{(1 + \beta t) \delta}$, where β repre-

sents the fraction $\frac{1}{273}$. Now the pressure measures the elastic force of the aerial particles: this elasticity cannot become negative, and ceases to exist when $p' = 0$, which may happen either because $(1 + \beta t') = 0$, or $\delta' = 0$. This last supposition would bring us to the consideration of the mathematical limits above treated on; the former, to the physical limits depending on the decrease of temperature at high altitudes, hence the air ceases to be an elastic fluid, according to this reasoning,

when $t' = -\frac{1}{\beta} = -\frac{800}{3} = -266\frac{2}{3}^\circ$ centigrade. Now the law of the decrement of heat in the atmosphere proceeds in a progression quicker than an arithmetical, and as the plane of perpetual snow is at a comparatively small altitude in climates of mean temperature, it is easy to see that from 100 to 200 miles altitude would be sufficient to diminish the temperature to the above number of 266° below zero. Even if the simple law $p = (1 + \beta t) \delta$ was not strictly rigorous at such low temperatures as -266° centigrade, still a diminution of temperature for a given density would produce a diminution of elasticity, and scarcely interfere with the general conclusion arrived at from that law.

But even limits thus obtained would, in all probability, be still too extensive, for it is not necessary that the elasticity should be totally destroyed: it is sufficient that the repulsive power of two contiguous particles of air at that altitude shall be less than the force of gravity, and if these two forces are equal, it will be the extreme extent at which the air can remain attached to the globe, leaving out of consideration the centrifugal force, which at that altitude is inconsiderable, and which would itself tend to remove those particles. Hence the limits become still more contracted by this consideration, and it will not be necessary that the temperature should be as low as -266° .

Some have imagined that planetary atmospheres are due to the attraction of the masses of the planets on a rare elastic fluid disseminated through space, but this supposition will not bear investigation; for putting aside the consideration of the extreme cold of the planetary spaces, this hypothesis is not corroborated by the dimensions of the atmospheres of the sun and planets, which would then depend on their masses, and the present total disappearance of the satellites of Jupiter behind their primary would be converted into an annular appearance round his body at the time of the eclipse of a satellite.

We have seen that the unequal distribution of heat in the atmosphere is a main source of the velocities and directions of winds, and consequently of the distribution of climate; but on the other hand, the earth itself, having its own distribution and radiation of heat, reacts on the atmosphere and produces dew, hoar-frost, &c. In like manner the sea and the Polar fields of ice materially affect the general distribution of heat.

The general causes of the temperature of the globe are the radiation of the sun, and the proper heat of the earth and its radiation; their effects however are greatly modified by various local circumstances, such as the vicinity of seas or mountains, and the difference in radiating power of the soil, together with the conducting powers of the strata subjacent to the particular places, with other causes less permanent.

With respect to the proper heat of the earth, we observe in any latitude that at a depth which is very small compared with the radius of the globe, the temperature is permanent throughout the year, the effects of solar radiation being confined to a superficial stratum of inconsiderable thickness. This fact has been fully established by long continued observations in the cellars of the Observatory at Paris, and by observations in the mines of Cornwall, in Scotland, and in other countries. If this stratum be supposed to be stripped off, the internal nucleus may be considered as nearly a

spherical mass, arrived at a permanent state of temperature in each part, and subject at its external surface to a given distribution of heat, or to a given power of exterior conductivity. The depth at which this permanence of temperature occurs is different in different latitudes, inasmuch as the solar action on the superior stratum is also different on account of the greater or less obliquity of its rays, and likewise on account of the earth's elliptic annual motion. Thus we have the following observed relations between the permanent temperatures and the corresponding latitudes:—

	Lat.	Permanent temperatures.
Equator	0°	78°
Cairo	30° 2	72° 50
Paris	48° 50	53° 60
Berlin	52° 40	49° 28
Vadso	70°	36°

The analytical equation for the propagation of heat in solids of any form, is—

$$\frac{dv}{dt} = K \left\{ \frac{d^2v}{dx^2} + \frac{d^2v}{dy^2} + \frac{d^2v}{dz^2} \right\},$$

where v represents the temperature at a point of which the rectangular co-ordinates are x, y, z , and the constant K depends on the interior conducting power, and t is the time. In the case of a sphere with a radius R , we may place the origin of co-ordinates at the centre, and transforming the above from rectangular to polar co-ordinates (namely, r , the distance from the centre, θ the angle formed by the radius vector with an axis, and ϕ the inclination of the plane of θ to one of the co-ordinate planes, the angles necessarily disappear from the transformed equation, and) it becomes

$$\frac{dv}{dt} = K \left\{ \frac{d^2v}{dr^2} + \frac{2}{r} \cdot \frac{dv}{dr} \right\},$$

on the supposition that the exterior permanent temperatures were uniform; to which we must annex the following equation for the surface, $\frac{dv}{dr} + h(v - a) = 0$, where a represents the temperature of the medium in contact with the globe, and h the index of exterior conductivity of the globe. But in the case of the earth both K and h are variable, and the former must then be brought under the sign of differentiation. After there shall have been a greater number of observations on the permanent interior temperatures of the earth, the above equations will be very useful in enabling us to calculate the temperatures at depths under the surface greater than it is probable man can ever penetrate, and they will assist in the explanation of the numerous phenomena which depend on the internal heat of various parts of the globe, as volcanoes, thermal springs, &c. Regarding the interior parts which are sufficiently remote from the surface as in a

state of permanent temperature, we should have $\frac{dv}{dt} = 0$; when the preceding equations admit of easy integration on the supposition that K is constant, and of approximate solutions on a probable form of the function K when variable. [REFRIGERATION OF THE GLOBE, and TEMPERATURE, TERRESTRIAL, DISTRIBUTION OF.]

With respect to the heat of the external stratum, it is principally dependent on the radiation of the sun, the effect of which depends on the duration and the obliquity of the solar rays, both of which are dependent on the declination of the sun and the latitude of the place. The integral taken throughout the year depends therefore solely on the latitude: from this integral the calculated mean temperature is derived, but differs in most cases from the observed inasmuch as the propagation of heat in the sea and in the air affects unequally those places in the same parallel which are near to or distant from the coasts, and the unequal quantity of continent in the northern and southern hemispheres produces a similar result with respect to them.

The direct heat of the sun being unequally distributed over different parts of the globe is the primary cause of the variation of climate; its diurnal action on land is sensible only for a few inches in depth; the annual action however extends throughout the superior stratum of variable temperature above mentioned. The mean temperature of a place is generally estimated by taking the average of the diurnal temperatures during the four seasons of the year, and again taking the average of these four averages.

As there is a great variety of temperature in the same parallel of latitude, we cannot have a formula dependent only on this element to express the heat of places on continents. The first approximate formula to that effect which deserves the name, is that given by Mayer, the celebrated astronomer; though empirical, it is found to possess considerable exactness. If t be the mean temperature in degrees of Fahrenheit's thermometer, he makes $t = 84 - 52 \sin^2 L$, where L is the latitude of the place. The supposed facts which evidently suggested this formula were the equatorial mean temperature of 84°, which is now generally supposed to be too high; the Polar mean temperature of 32°, or the freezing point, which, from the recent observations of Parry, Scoresby, &c., is now known to be far too great; and thirdly, that the diminution of heat from the equator to the poles

must proceed according to some even power of the latitude in order to amount to the same quantity in equal latitudes north and south, for which reason he chose the least even positive power of the sine. However, since the quantity of land in the northern hemisphere is about three times as great as in the southern, the solar heat accumulates more in the former, and in the latter is more equable between winter and summer. Sir D. Brewster has substituted for Mayer's the formula $t = 81.50 \cos L$, which bears an exceedingly good comparison with observations, but for the reasons above given he has found it necessary to modify it for the New World. Mr. Atkinson has shown that the mean of the errors of Mayer's and Brewster's formulæ for ten places nearly on the level of the sea are respectively + 1° 72 and - 12. The temperatures of April and October are generally nearly the mean of the year, which also is found to vary but little in a considerable succession of years. If τ be the mean temperature at an altitude h in feet, in a given place where t is the temperature of the surface, to express τ ,

Mr. Atkinson has proposed the formula $\tau = t - \frac{h}{251 + \frac{h}{200}}$, giving for the

extreme atmospheric cold the temperature - 200°, which is probably near the truth.

The names of Isothermal, Isocheimal, and Isothermal lines have been given to lines passing through places which have equal mean summer, winter, or annual temperatures, the two former having contrary courses, and the third intermediate. The difference of latitude between places in the New and Old Worlds, on the same isothermal line, is considerable, as appears from the following table:—

Isothermal line of Temperature.	Places.	Latitude.	Longitude.
32°	Near Uleo, Lapland, and Table Bay, Labrador	67°	20° E.
41°	Stockholm and St. George's Bay, Newfoundland	54°	58° W.
50°	Belgium and Boston, U. S.	60°	18° E.
59°	Near Rome and Raleigh, N. Carolina	48°	59° W.
		51°	2° E.
		42½°	71° W.
		43°	11½° E.
		36°	76½° W.

or we may average according to latitude thus:—

Latitude.	Mean Temperature of West of Old World.	Mean Temperature of East of New World.
30°	70.52	66.92
40°	63.14	54.50
50°	50.90	37.94
60°	40.64	23.72

The mean temperature in the latitude of 34° in different continents, and at places near the sea, is found to vary but little, thus:—

Places.	Continents.	Latitudes.	Temperature.
Cape of Good Hope	Africa	33° 51'	66° 7
Port Jackson, N. Holland	Australia	33° 53'	66° 9
City of Buenos Ayres	America	34° 36'	67° 5

The sea varies in temperature much less than the air; the region of warmest water extends about 5½° on each side of the equator, but rather farther to the south than to the north. There are two points of maximum cold near the North Pole; one of 3½° Fahr. in the neighbourhood of Melville Island, and another of 2° Fahr. somewhere about the 79th degree of north lat., long. 120° east. The isothermal curves, "accordingly, about the North Pole bear no inapt resemblance," as remarked by Sir David Brewster, "to the isochromatic lines, or coloured sphæro-lemniscates exhibited by polarised light in a biaxial crystal, whose optic axes are inclined to each other about 30°, having the pole itself almost centrally situated between them, and their line of junction nearly coincident with that diameter of the polar basin which intersects it, and passes through its two great outlets into the Pacific and Atlantic oceans—a most remarkable feature, strongly indicative of the absence of land, and of the prevalence of a materially milder temperature (possibly not averaging below 15° Fahr.) at the actual pole. Of the point or points of maximum cold in the southern hemisphere we know nothing." An unexpected and most interesting consequence has followed from Sir D. Brewster's recognition of the resemblance of the north polar isothermal curves to the isochromatic lines of polarised light in the case described. Sir John F. W. Herschel has found that there is a coincidence between the two sets of curves, "in respect of the arithmetical progression of temperature in the one series corresponding to that of chromatic sequence in the other," which he points out "as something different from and additional to a mere general resemblance of form;" though "it will of course be understood," as he observes, "that we have not the slightest intention of tracing any physical analogy" between them. What the relation can be, of which this coincidence is a result, it is impossible to say; but it

is important in this place to indicate the bearing of the coincidence upon Mayer's formula, expressing the diminution of heat from the equator to the pole. Sir J. Herschel shows that if a series of curves be traced by calculation from an equation derived from and equivalent to the general equation of the optical curves in question, for temperatures varying from a certain mean temperature thermometrically indicated, and from each other, by equal thermometric intervals, these curves, "in respect of their magnitudes, distances from their foci and the pole, as well as in their general gradations of flexure, will coincide, or nearly so, with a series of isochromatic curves *equidistant in their orders of tint*." This latter series, if laid down on a map, will divide the meridians in the polar regions in a succession of points distributed over them according to a certain law of progression. By calculation from these data, he obtains equations, of which he says: "Now it is remarkable that this is precisely the form in which Mayer endeavoured to express empirically the decrement of temperature in proceeding from the equator towards the pole, from such observations as could be obtained about the middle of the last century." The details of this curious subject are given by Sir J. Herschel in his article Meteorology, 'Encyc. Brit.' pars. 192 to 194.

The production of winds, we have already stated, is mainly attributable to the unequal distribution of heat in the atmosphere. The attractive action of the sun and moon on that fluid, though producing atmospheric tides, which are believed to have been recognised by barometrical observations, could only produce a tropical wind with a velocity of 4 miles per day, which would be evidently inappreciable amongst the numerous disturbances arising from temperature; but the heating action of the sun in tropical climates produces some well-known winds in the following manner.

On account of the annual accumulation of heat from the solar rays between the tropics, two currents of air from the north and south rush forward to occupy the place of the rarified air of this region. Now since the earth in its diurnal rotation moves from west to east, these currents appear to deflect to the west on account of the increased velocity of the parallels of latitude near the equator, which have greater radii than the arctic parallels, the apparent excess of motion towards the west being the excess of the space described in rotation by the equinoctial above that described by the tropical and even polar circles; the velocities perpendicular to the equator, being nearly equal and contrary, produce no sensible wind, but those parallel to it produce a wind directly west and enduring, called the "trade-wind," with this exception, that the northern hemisphere being the warmer, the resultant is a few degrees north of the equator, crossing the Atlantic from Africa to Brazil, and the Pacific from Panama to the Philippine Isles, and the Indian seas from Sumatra to Zanguebar. But when the continents stretch into the torrid zone, the local accumulation of heat being great, two opposite periodical winds, known by the name of *monsoons*, are produced, approaching the north tropic in summer, and the south in winter, and blowing in the Arabian and Indian seas north-west from April to October, and in the contrary direction during the rest of the year: the reverse occurs south of the equator.

Now as the cold air rushes into the tropical regions, expelling the warm air of that locality between 28° on each side, the warm air forms a counter-current, still possessing equatorial velocity, and produces in both hemispheres exceeding the above latitude a westerly and genial breeze, which is felt during three-quarters of the year from Newfoundland to the west of England, and from South America to the Cape of Good Hope. On the same principle the easterly, or rather north-easterly winds originate in the polar currents, and are piercingly cold in general. The great radiation of arid plains produces many local winds, such as the *sirocco* from Africa to Italy, and the destructive *simoom* of Arabia, &c., but they do not depend on general atmospheric causes.

The greater number of the several subjects the knowledge of which constitutes the science of Meteorology, will be found distributed throughout this division of the 'English Cyclopædia' in alphabetical order. But it may be useful to the reader and student to refer to the more important of them in this place, arranged under the heads of the principal branches of the science. That of the form, general nature, and extent of the gaseous envelope of the earth is treated of under *ATMOSPHERE*, and partially returned to in the article *COMETS*, *Physical Constitution of*. In the first-named article, and also under *AIR*, its chemical nature and relations are described, and its agency in changing the condition of the bodies composing the earth's surface and employed in human constructions, under *ATMOSPHERIC INFLUENCE*. The articles *ACTINOMETER*, *TEMPERATURE*, and *THERMOMETER*, belong, the first entirely, and the latter in part, to its relations to heat; while some consequences of its action on light are described in those of *AÉRIAL PERSPECTIVE*; *REFLECTION* and *REFRACTION*, *ATMOSPHERIC*; and *TWILIGHT*. The subject of the pressure of the atmosphere and its variations, and their connection with the weather, are explained under *BAROMETER*; *BOILING OF LIQUIDS*; and *MANOMETER*. The consequences of the changes induced by variations of temperature in the aqueous constituent of the air, forming so important a branch of practical Meteorology, are described under the following heads: *CLOUDS*; *DEW*; *DEW-POINT*; *EVAPORATION*; *HAIL*; *HOAR-FROST*; *HYGROMETER* and *HYGROMETRY*; *MIST*; *RAIN*; *RAIN-GAUGE*; *SNOW*; *THAW*. The phenomena dependent upon the mechanical affections of the air,

and the philosophy of winds, storms, and cyclones, are treated of in the articles *AÉRO-DYNAMICS*; *AIR*; *ANEMOMETER*; *ATMOSPHERE*; *CALMS*; *FLUIDS*, *ELASTIC*; *MONSOON*; *SAMIÉLI*; *SIROCCO*; *TORNADO*; *TYPHOON*; *WHIRLWIND*; *WIND*. The electrical part of meteorology will be found under *ELECTRICAL LIGHT*; *ELECTRICITY*, *ATMOSPHERIC*; and *LIGHTNING*; a certain subject relating to this branch of the subject being also noticed under *BREATH-FIGURES*. *CLIMATE* and *WEATHER*, and the special subjects of *DUST*, *ATMOSPHERIC*; *IGNIS FATUUS*; *METEORS*, *IGNEOUS* or *LUMINOUS*; and *POLAR LIGHTS*, are discussed under those heads.

METEORS, IGNEOUS or LUMINOUS. The following is a condensed statement of the present condition of knowledge in the department of meteorology relating to these objects, which may now not improperly be termed meteoric astronomy, and which is connected in a remarkable manner with cosmical science, and also with almost every branch of physics and of the study of inorganic nature.

The spaces through which the bodies of the solar system and the comets revolve about the sun, appear also to be traversed by celestial bodies comparatively minute, but in number incalculable; which, in common with the smaller true planets of the system have received from certain astronomers and physicists the appellation of *Asteroids*, or star-like bodies—the word star being taken in its universal and ancient sense of any luminous object seen in the heavens.. [*ASTERIODS.*] Zones of these bodies, consisting of countless myriads of them, we have much reason to infer, revolve about the sun in nearly their own planes, or in some plane which they include; and certain astronomers consider that some of them have been proved to be minute satellites of the earth, as was believed, indeed, early in the scientific history of this subject.

These smaller asteroids, when they approach within a certain comparatively small distance from the earth, are, or subsequently become, the objects termed shooting-stars, fire-balls, and igneous meteors; new series of phenomena being successively presented by them as they come nearer to the earth's surface, and especially in many instances, in consequence of their finally passing through a great extent of the atmosphere in an oblique direction, so as to experience the effects of its increasing density, both physical and chemical, throughout a trajectory of great length. But in this general statement it is not pretended to deny that objects and phenomena very different in their origin and nature, as well from each other as from those now under review, may probably be included also under the popular or only half-scientific designations of meteors and shooting-stars.

The appearance of these meteors is in many cases attended or succeeded by the fall of solid bodies, either stones or metallic iron, or in some cases both mingled together in the same block, forming a series of bodies collectively termed *Meteorites* (or *AEROLITES*, in *NAT. HIST. DIV.*), consisting, mineralogically, of two principal groups, graduating into each other, namely, meteoric stones, and meteoric iron; and which have also received the appellation of *Meteoric Rocks* in the classification of the mineral aggregates to which the term *rock* has in modern science been extended.

The visible meteor, when observed at those distances which must be within the atmosphere, must consist of flame or gaseous matter in an ignited or incandescent state, and undergoing combustion; but arising, as may be inferred from Sir H. Davy's researches on flame, not from the combustion of matter which under ordinary circumstances can exist in a gaseous state at the surface of the earth; but from that of matter which is there solid, consisting, doubtless, of the metallic or other combustible bases which meteorites are found to contain. Among these, it may be remarked, are sulphur and phosphorus, both which Davy particularised as capable of combustion in air rarefied to a degree equal to that of the regions of the atmosphere in which meteors had been observed to display their phenomena. No particular stress, however, can be laid upon this circumstance, as meteorites contain other combustible bases which very probably have the same property, including the metal magnesium, an element of almost every meteoric stone, in considerable proportions. The extraordinary intensity of light also which attends the combustion of magnesium in oxygen, may be connected with the brilliant phenomena of the meteors.

The luminous extensions in the directions opposite to that of the meteor's motions, ordinarily called tails, as observed in many, if not in all igneous meteors, are manifestly referable to the elongation of the mass of flame constituting the visible meteor, by the resistance of the atmosphere to their progress through it with planetary velocity, as well as in some degree by the adhesion of the air to it; the passage from the intense white light of the head or body and proximate portions of the tail, to the red light of the distant and extreme portions of the latter, being attributable to the cooling down of the flame during its course, and in proportion to its distance from the most intensely heated part of the meteor.

It would appear, both from theory and observation, that the figure of the meteors must approach in their course more or less closely to that of the solid of least resistance. The meteorites which fall, or are cast down from them, when unbroken, especially those consisting of metallic iron, retain approximately the form which had thus been imparted to the meteors of which they were the nuclei, by the resistance of the air,—a form resembling that of the more perfect volcanic

bombs, and which they have received from the same cause. These effects of the resistance of the atmosphere to the meteor's motion were first pointed out by Mr. Brayley.

The persistent track or trail of less vivid light often continuing to be seen for several minutes, or for a considerable fraction of an hour, or even for more than an hour, after the disappearance of the meteor itself, must be attributed to the deposition in the atmosphere, in the meteor's path, of a kind of beam of finely-divided solid matter, mingled probably with vapour, and no doubt in part produced by the condensation of vapour resulting from the combustion proceeding in the meteor, and the particles of which, being originally deposited at insensible distances from each other, continue to preserve, during their slow and uniform descent in the tranquil regions of the air where they originate, the aggregate form in which they were deposited; while the low conducting power for heat of the rare atmosphere permits them to retain their high temperature and consequent luminosity for a comparatively long period of time. The continued action of gravity, and the disturbing agency of currents in the lower regions of the atmosphere will, however, eventually convert the at first rectilinear beam into a more or less curved and waved figure, and at length produce the serpent of fire of the superstitious ages, accurately reproduced in the case of the meteor of the 7th January, 1856, as witnessed at Tunbridge Wells, and represented by a correspondent of the 'Illustrated London News,' of the 12th. These views are supported by reference to telescopic observations of the trails, particularly by those of the late Professor Pictet, of that left visible for seven or eight minutes by the meteor seen in France and Switzerland on the 15th of May, 1811, the most luminous part of which "did not appear to be continuous, but composed of distinct and separate particles."

The production, continuance, gradual change of form and descent, and final dissolution of these trails, may be familiarly, but correctly, illustrated by comparison with the similar succession of phenomena characterising the trail of smoke and soot issuing from the funnel of a steam ship during its progress on its course, in which also a rectilinear beam of finely divided solid matter separated from flame and smoke, and often several miles in length, becomes a persistent trail, and gradually changes into a waved or serpentine form. In many cases the trail of a meteor must have been originally a cylindrical beam, constituted as now explained, having a diameter of many hundred yards (equal to or greater than that of the meteor itself), and a length of many miles, deposited in an inclined direction, at heights of some miles above the earth's surface.*

An objection founded on the assumed solidity of the particles, and the considerable specific gravity which must be attributed to them as results of the combustion going on within the meteors, which, it might be inferred are inconsistent with their long suspension in the manner supposed, is at once obviated by applying to the subject the results of Professor Stokes's researches on the effects of the internal friction of fluids as applied by himself to the suspension of fine powders in a fluid of widely different specific gravity, and to that of the suspension in the air of the minute globules of water constituting the clouds. [CLOUDS.] The trails of meteors are suspended like the clouds, though, at first, probably, in higher regions of the atmosphere, and like them they consist of excessively minute particles, which, as in all probability their dimensions will be very nearly the same in all directions, may be regarded as spherules also, and will consequently be suspended temporarily, like the globules of the clouds, by the resistance to their downward motion arising from the internal friction of the air. The degree in which they partake of the projectile motion of the meteor itself, will also tend to their longer suspension, by converting the perpendicular fall which the mere action of gravity would cause into an oblique curvilinear descent.

The two great causes of all the phenomena now described, are evidently the motion and the heat of the meteors. The origin of the former is doubtless involved in that of the portions of matter constituting the nuclei of the meteors themselves, a subject noticed below. Dr. Chladni, the earliest philosophical investigator of the subject of meteors and meteorites (as a whole), and in later times Sir H. Davy, and Sir John F. W. Herschel, have ascribed the heat to the compression and friction of the air, resulting from the enormous velocity, of from six to thirty miles in a second, or more, of the meteors, supposed to be solid when they enter the atmosphere. Still more recently, in a paper read before the Royal Society on the 19th of June, 1856, Dr. Joule and Professor William Thomson have inferred from their own experiments on the thermal effects of fluids in motion, to which those of solids carried through fluids must be equivalent, the great probability that meteors really acquire all the heat they manifest from the friction of the air. In a communication made by Dr. Joule to the Section of Mathematics and Physics of the British Association, in 1859, he affirms, reasoning from the concluding series of experiments

* These views of the physical constitution of meteors and their trails were in substance originally stated by Mr. Brayley, in a paper read in 1824 before the Meteorological Society then recently formed, and published in the 'Philosophical Magazine,' 1st series, vol. lxiv., p. 288, &c. With additions and modifications required by the progress of science, they have been subsequently often repeated by him, in lectures delivered at the Royal Institution, and in several courses at the London Institution.

on the heat developed by friction in air, made by him and Professor Thomson, that "there remains no doubt whatever as to the real nature of 'shooting stars.' These," he says, "are small bodies which come into the earth's atmosphere at velocities of perhaps twenty miles per second. The instant they touch the atmosphere their surfaces are immediately heated far beyond the point of fusion, or even of volatilisation, and the consequence is, that they are speedily and completely burnt down and reduced to impalpable oxides." If this be true, the persistent trails of igneous meteors, which are left in the sky equally by the smaller as by the larger, (though continuing, with the former, for a much shorter space of time,) will consist of the particles of these oxides, or perhaps of particles condensed from the vapour into which the oxides are first converted; agreeably to the explanation of their nature already given in this article, as derived long ago from applying the facts made known by Davy, relative to combustion in rarefied air, to the observed phenomena of meteors.

In the present state of cosmical and meteorological science, it is unnecessary to enter upon the question of the origin of meteors and meteorites further than to urge, that, the computed enormous magnitude of the former,—the actual diameter of the visible meteor, however constituted, being often many hundred yards, while in some instances its dimensions must probably be expressed in miles,—their planetary velocity and the pregnant fact that they give out a more intense light than any objects in nature except the sun, (an assemblage of characters explicitly claimed by the writer of this article for the particular meteors from which meteorites have been observed to descend, as well as for many, if not all of those from which their fall is not known), must at once disprove nearly all the hypotheses which have been framed specifically to explain the origin of meteorites; and especially, among others, that of their projection from lunar volcanoes. The cogency of this argument will remain essentially unimpaired if it shall be found, according to recent suggestions, that the actual magnitude of many of the meteors is considerably less than that hitherto ascribed to them. The problem of their origin must in fact, be regarded as the same with that of the origin of the greater asteroids and planets themselves.

It is right to state that Mr. R. P. Greg, F.G.S., who has given much attention to the subject, is of opinion that there is a distinction between luminous meteors and those from which meteorites have fallen; an opinion which, so far as the (apparently) smaller meteors called shooting stars are concerned, he shares with the American Professor Olmsted and others. Mr. Greg is the author of a valuable essay on meteorites, entitled 'Observations on Meteorolites or Aërolites, considered Geographically, Statistically, and Cosmically; accompanied by a complete Catalogue of Meteoric Falls.' It was first published in the 'Philosophical Magazine' for November and December, 1854, and in a separate form in November of the following year.

The views of the entire subject which have been enunciated in this article, have resulted from long attention to it by the writer. Others will be found, together with an invaluable assemblage of facts, in Arago's 'Astronomie Populaire,' liv. xxvi.; 'Météores Cosmiques,' tome iv., p. 181-322; and also in the reports on meteors annually communicated for some years past to the reports of the British Association by the late Professor the Rev. Baden Powell.

The purely physical history of the subject having now been generally considered, we may proceed to notice the manner in which the extraordinary relations produced in former times, of the appearance in the sky of blazing torches, sceptres, bundles of rods, fiery swords, trumpets, and other objects, may be rationally interpreted, agreeably to our present knowledge of meteoric phenomena. This subject belongs to a field in the history of science and literature hitherto but little cultivated. It may be elucidated by examining the figures and accounts of such appearances which are given in the works of old writers, especially in those of Zahn, Conrad Wolfhart, and their contemporaries, and also by Ambrose Parey, and comparing them with similar phenomena as witnessed in more modern times, and depicted by observers whose only object was to represent the actual configuration of the luminous appearances.

The circumstance that from the enormous rapidity of the meteors all the visible phenomena (except the persistent trail) would have been seen and have ceased to appear within the limits of a few seconds of time (so that in all cases the figures must have been produced from memory alone), which must have led to the representation of many appearances as simultaneous that in reality occurred in succession, and the manner in which, during the transit of the meteor, impressions on the retina of past phenomena must have been mingled with those actually present, have led to the production of many of the singular representations that are extant. It would not be difficult to trace the mental process by which natural objects, thus witnessed for a few seconds only, would by uninformed observers, prepared to regard them with superstition, be supposed to be really preternatural types of the familiar objects to which the outlines of their forms were comparable; the meteors, thus supposed to be torches, swords, and the like, would naturally be described and depicted with all the appendages and accompaniments of those objects. These accompaniments, however, were not in all cases merely suppositions, as may be evinced by reference to the great meteor of 1758, which exemplified the ringed sceptre of the mediæval figures, the rings on the shaft being manifestly the smaller

meteors, the production of which is the first visible result of the explosion, seen as projected upon the tail of the parent meteor; either because, as is evidently the fact in many instances, they were really enveloped in the flames composing it, or on account of the blending upon the retina of the observer of past and actual appearances. The fiery sword dipped in blood is the meteor in its normal form, at the middle of its visible course, the distant part of the tail shining with red light, being cooled down to the temperature of simple ignition, as already indicated. In a similar manner, the bull's heads, flying eagles, and other monstrous appearances, may be consistently explained, care being taken, when the authorities permit, to identify them with the actual meteor otherwise recorded. The blazing and interlaced serpents moving in the air may be explained by reference to the actual phenomena of the persistent tracks or trails already described, as witnessed in various cases by Pictet and others, as well as by the published representations of the meteor of January 7th, 1856. One instance may be cited, in which a large and beautiful luminous serpentine train continued for some minutes after the disappearance of a meteor which threw down a stone at Angers, in 1822. The ensanguined tresses attached to blazing stars are evidently the trails under another phase, and in their later condition, emitting red light only, but retaining their linear or band-like form. The *Lampades volantes* and *Dracones volantes* of former ages may be similarly understood, by reference to other characters and phenomena of meteors; one of the contemporary figures of the fire-ball seen in London on November 13th, 1803 (described under other phases by Dr. Firminger, in the 'Philosophical Magazine' for the following year), exemplifies the particular configuration of the meteors to which the latter appellation was given: it is contained in Nicholson's 'Philosophical Journal' for 1804.

METHIONIC ACID ($C_2H_2S_4O_{10}, 2HO$), *Disulphometholic Acid*. This acid is obtained by heating cyanide of methyl with concentrated sulphuric acid:

It is only of theoretical importance.

METHODISM, a very memorable word in the English vocabulary, as the thing signified is also very memorable in the history of the Christian church, and especially of that part of it which consists of inhabitants of the British Isles.

The people of England have been described by foreign writers as being beyond all other nations *religiosissimi*, or very strongly devoted to religious thoughts and exercises. The success of Christianity on its introduction into this island is one proof of it; but still more is the great encouragement given to the religious orders, and the multitude of churches which were erected in the very earliest periods. A few centuries later, we have the proof which is afforded by the great encouragement which the different orders of friars received, who were a species of Methodist preachers of the middle ages.

Each century seems to have had its schism arising in this national characteristic. In the 15th there were the *Lollards*, who were easily put down by the Church; in the 16th, the *Gospellers*, who, having the court with them, brought about the Reformation; in the 17th, the *Puritans*, who were for a short time triumphant, but who were finally reduced to the several denominations of dissenters still existing, the *Presbyterian*, the *Independent*, the *Baptist*, and the *Quakers*. In the 18th century, when not only the Church but the several dissenting bodies were thought by many to have lost much of the spirit and fervour of religion, there arose the *Methodists*, who, being allowed to proceed unmolested, have produced, without having attempted to overturn the Church, no small change in it, in modifying its ministrations, in calling back attention to the supposed doctrines of its founders, and in rousing its ministers to more strenuous exertions.

It is interesting to observe the various forms in which Methodism is presented, and we see it more strikingly in the various sects which are called the Methodist sects, and which are in fact so many different classes of persons who collectively are called Methodists. There are:—1, the Wesleyan Methodists; 2, the Methodists of Lady Huntingdon's Connexion; 3, the Methodists of the New Connexion; 4, the Primitive Methodists; 5, the Bible Christians; 6, Protestant Methodists; 7, Association Methodists, now united with a portion of the Wesleyan Reformers, under the designation of the "United Methodist Free Church;" 8, the Inghamites; 9, the Wesleyan Reform Union, comprising those Reformers who declined to form part of the United Methodist Free Church. There is also a large body of persons, chiefly in Wales, calling themselves Calvinistic Methodists, who are not included in what is called Lady Huntingdon's Connexion.

The year 1729 is considered as the time at which Methodism began. It is not intended in this article to give a biographical notice of the founder of Methodism. This will be found in its more appropriate place. [WESLEY, in BIOG. DIV.] Under the word WHITEFIELD, in BIOG. DIV., will also be found a notice of George Whitefield, another student at Oxford, who joined the Wesleys in 1732, and who had a large share with them in laying the foundation of Methodism. It may suffice for the present to say that the Wesleys and Whitefield, instead of following the usual course of clergymen, in settling down on livings,

after studying in the university, undertook the wider duty of rousing their countrymen generally to a higher tone of devotional feeling, and to a regard to the doctrines of the Church, to which there was then, owing in a great measure to the writings of the Latitudinarian divines, and other writers, a growing indifference. Many were of opinion that the all-in-all in Christianity was the doing justly, loving mercy, and walking humbly, looking for that blessed hope and glorious appearing of our Lord and Saviour Jesus Christ, when every man should receive according to his works. Wesley went forth proclaiming that he came to call men back to *old Church of England principles*. This was his favourite phrase, as appears by many passages in his journals, and this object (at first, at least) was what he himself considered the chief purpose of his mission. What he meant was original sin, regeneration, the atonement by the blood of Christ, the influence of the Spirit, justification by faith, freedom of the will, accountability, and eternal reward or suffering; Whitefield added to these the eternal decrees, the extreme doctrines of Calvinism.

The object of neither of them was to be founders of sects out of the Church, but to produce a change within the Church. It was soon however manifest that their end could not be attained by remaining, even outwardly, conformable to the rules of the Church in regard to its ministers. The doors of the parish churches were soon closed against them, and the meeting-houses of the dissenters were closed likewise. They then preached wherever a congregation could be gathered together, in rooms or in the open air, and preaching with the zeal and energy of the Apostles, it was in vain, with a population like the English, to attempt to prevent them from making a deep impression. Such energy of preaching had not been witnessed since the time of the old Puritans. The effect indeed may be described as marvellous. The cry, "What shall I do to be saved?" was heard from many voices wherever they had an audience; sometimes this cry was accompanied by dreadful shriekings and faintings. The accounts given by friends and enemies are in respect of this the same. Many well-meaning persons regarded it only as a mischievous enthusiasm. By the profane the preachers were not unfrequently assaulted, and their lives placed in jeopardy. But many were soon found ready to assist them in their work, either by forming into societies persons convinced by them, and erecting chapels for their assembling together, or by taking upon themselves the office of teacher, and following in the track which their masters had trod. There were at the same time a few persons who were ministers in the Church, and who did not leave the parishes in which they were settled, who seconded the labours of these men. Such were Fletcher, Sellon, Perronet, Dickinson, Venn, Grimshaw, and others.

Whitefield died early, worn out by his extraordinary exertion. He was the founder of the Calvinistic section of Methodists. Of this sect of Methodists the original chapels have become, not adopting any connexional bond, Independents; but from it arose two separate sects, the Countess of Huntingdon's connexion, and the Welsh Calvinistic Methodists. The first has an endowed college at Cheshunt for the education of its ministers, with 109 chapels (accommodating 38,727 persons, at the census of 1851), in many of which the ritual of the church of England is used in a modified form. On Sunday, March 31, 1851, the attendance was, in the morning 21,103; afternoon, 4380; and in the evening 19,159. The Welsh Calvinists at the same dates had 828 chapels, with accommodation for 211,951 persons; and the attendance was, morning, 79,728; afternoon, 59,140; evening, 125,244. In 1853 they had 207 ministers, 234 lay preachers, and 58,577 communicants.

The life of Wesley was prolonged to his eighty-seventh year; and when he died, which was in March, 1791, he had been sixty-five years in the ministry, and fifty-two years an itinerant preacher; he lived also to see in Great Britain and Ireland about three hundred itinerant preachers and a thousand of what are called local preachers "raised up from the midst of his own people," and eighty thousand persons in the societies under his care. Such was the state of this one principal branch of Methodism at the time of Wesley's decease. Some thought that as it had grown with him, it would die with him: but they were mistaken. He had provided (as far as human means go) for its perpetuity by binding up his members in a church, with a frame and constitution as strong as could be given to it by subordination, authority, rules, common interest, and the bond of common property. Thoroughly regardless of accumulating personal wealth, the contributions of the members of his societies, which had long far exceeded the expenses, enabled him to transfer to the body of preachers, in whom, as in an assembly of presbyters, he vested it, whatever interest he had in a multitude of chapels in every part of England, and a large surplus fund; and this property, it is understood, has gone on year by year constantly increasing, notwithstanding the vast exertions which have been made in the erection of chapels, schools, and other buildings, the support of an additional number of preachers, and in missionary exertions among the people not yet converted to Christianity. It was in 1738 that the first Methodist society was formed by Wesley himself on his return from Hernhut in Germany, and in 1739 there were several chapels in London, the principal one being in Fetter Lane. In 1740 Whitefield separated from them. In 1743 the rules, which still continue in force, were drawn up for the London and other societies, especially those of Bristol and Kingswood, the part of the kingdom in which, at the beginning of his ministry, Wesley had chiefly laboured. These

rules set forth, that the Methodists are a people who, in addition to the form of Christianity, seek the power of godliness, and manifest it by good works: the societies are united, that by counsel, exhortation, and prayer, they may assist each other in the great work of religion.

We proceed to describe the constitution of these societies and of the general union of them, forming the highly important class of Christians called the Wesleyan Methodists.

These societies are divided into classes of twelve persons generally, but sometimes more, and he that is supposed the best qualified by mental and religious excellency, is appointed the leader. His duty is to see his members weekly, to receive the voluntary contributions of his class, and to take the amount to what is termed the "leaders' meeting;" that is, the stated meetings of all the leaders and the society-stewards in a certain locality, where the society of the place is represented, and its affairs transacted. The society-stewards take the moneys from the leaders, pay the ministers their weekly stipend, and take the surplus to the circuit-stewards at the quarterly meeting. In the leaders' meetings are stewards for the poor also, who at the direction of the meeting give to the leaders, for their poorer members, whatever funds may be furnished by any society and congregation for that purpose.

A number of these united societies lying around some central town or large chapel is known as a circuit. The villages or chapels in the vicinity of the centre are regularly visited by the ministers at stated times for the purpose of conducting worship, and the discharge of other pastoral duties. In the origin of Methodism these circuits included not merely one county, but sometimes parts of several; but now, owing to the spread of Methodism, the circuits are limited to a diameter of twenty, ten, and in some cases of fewer miles. The societies and congregations in these circuits are committed to the care of the ministers yearly appointed by the Conference; and more especially to one who is termed the superintendent: generally, when compared with his fellow-ministers in the same circuit, he is of the longest standing in the connection, but not always so, as the Conference claims the right of appointing to this office the person whom it judges the most proper. To the superintendent principally the direction of the other ministers is committed, as well as that of the local preachers also, who are men in business and only occasional preachers; and in addition to the above, the superintendent has the care of the leaders, stewards, and, in one sentence, the whole circuit: he is accountable to the Conference for the use of the power committed to him.

At the May district-meeting, when the circuit-stewards have taken their departure, one of its ministers is chosen by ballot, as its general representative at the coming Conference. Then the meeting determines how many additional ministers belonging to the district shall be allowed to proceed to the Conference. The Conference, strictly and truly, consists only of one hundred preachers, whose names are in the deed that gives it a legal existence, but all the preachers allowed to go from the respective districts are suffered to sit therein, and vote as integral parts thereof. At the assembling of the Conference, one of its first acts is the choosing by ballot the president and secretary, who must be of the hundred—the legal Conference. The business which follows comprises the supplying of the places of those who by death, &c., have been removed, by the hundred, partly by ballot and partly by nomination; the examination of the character of every minister as to his moral conduct, Methodistical orthodoxy, &c.; the examination of the minutes of the several districts; and the appointments of the ministers for the coming year. Further, they legislate for, and determine the multifarious concerns of the connexion.

In Methodism, the members are divided into two great classes—the ministers and the people; and each, if accused, is tried at its separate tribunal, and by its own peers. The members are tried by the leaders' meeting; and the ministers by the ministers only, at a district-meeting. If either the members or ministers are dissatisfied with the decision of their respective judicatories, they may appeal to the Conference, the highest court of Methodism.

Methodism furnishes its ministers from the members, who first are known as local preachers, and then nominated at the March quarterly meeting as persons proper to be recommended for examination at the coming May district-meeting by the ministers alone. If the churches in the circuit, by their representatives at the quarterly meeting, recommend the person nominated, he appears before the district-meeting and undergoes an examination as to his personal acquaintance with Christianity, his Methodistic orthodoxy, and attachment to its discipline. If approved and recommended by the district-meeting, his name is brought before the next Conference. If all inquiries here are satisfactorily met, he is either immediately employed as a probationer, in which state he must continue for four years, before he can be admitted into full connection—that is, be ordained and permitted to administer the sacraments—or he may be placed on the list of reserve, and if approved, when again examined by the preachers in the London district, he will be admitted to the Theological Institution, and by training for some two or three years, be prepared for his work.

The doctrinal test of the Methodists is found in certain volumes of Mr. Wesley's Sermons, and his notes on the New Testament. Among the most prominent of these doctrines, next to the being of God, his perfections and worship, are—original sin, moral impotency, the sufficiency of grace, the atonement, general redemption, justification

by faith, the witness and work of the Spirit, entire regeneration, good works as the fruits thereof, eternal life, and everlasting punishment.

The disciplinary test is found in the minutes of Conferences, the statute-books of the Wesleyans. While the ministers appointed by the Conference keep within the above limits, they have a right to the pulpits, and are beyond control. But any departure from the above will give authority to the trustees of any chapel in which un-Methodistical doctrine is preached, to require the chairman of that district to summon the ministers of the district, and the trustees of the circuit in which the supposed transgressor is found, and if at the district meeting so constituted his delinquency be proved, he may be suspended until the next Conference, when the whole case will be reviewed, and finally adjudicated.

While the ministers are irreproachable, the Conference claims the right of appointing them to all the chapels in the connection settled on the Conference plan, and this right is beyond dispute or control; but over the property of the chapels, the Conference has no control, except it be the giving or withholding permission to the trustees to sell, when this is craved by them.

The labours of Wesley were not wholly confined to England. He had made little impression upon Scotland, where the number of members at the time of his decease scarcely exceeded a thousand. But in Ireland he had about fifteen thousand, and in the United States there were about thirty thousand. Since his decease, the prevalence of Wesleyan Methodism in North America has been very great.

By the census of 1851, there were 428 circuits in Great Britain, with 1024 ordained preachers, and between 13,000 and 14,000 lay preachers, who receive no remuneration, and there were 6579 chapels in England and Wales, with accommodation for 1,447,580 persons. The number of communicants was 358,277. On Sunday, March 31, 1851, the attendance at these chapels (including an estimate for 133, from which no returns were made), was—morning, 429,714; afternoon, 383,694; evening, 667,850.

The number of Scotch chapels by the census return was 82, of which 65 were open in the morning, 31 only in the afternoon, and 64 in the evening; the attendance was 8937 in the morning, 2563 in the afternoon, and 9516 in the evening; but there is accommodation for 22,441. The separation of the Wesleyan reformers, however, in 1850 and 1851, reduced the number of communicants in England and Wales to 270,265. In 1860 the returns to Conference show the members in society in Great Britain to be 277,589, with 26,683 members on trial, and 121,760 scholars.

In 1793 great dissensions existed about the sacraments, whether they should or should not be administered by the ministers, in the chapels, to the members of the society who required them as a part of Christianity. This led to secessions at Bristol and elsewhere. In 1795 many influential societies chose delegates, and sent them to the Conference then held at Manchester, for the purpose of claiming some share in the government of Methodism. This led to concessions as they may be found in the Plan of Pacification,—the Bill of Rights of the Methodists.

With these concessions many were not satisfied, and, being led principally by the Rev. Alexander Kilham, they seceded in 1797, and formed the *New Connexion*, a truly respectable body, who, in 1853, had 301 chapels, 95 circuits, 814 local preachers, and 16,070 members. In the report of the Conference of 1860, the total number of chapels, including Ireland and Canada, is stated as 473, preachers, 189; local preachers, 1204; members, 29,331; on probation, 2562; there were also 60,753 scholars attending their schools. Mr. O'Bryan, of the North Cornwall district, was the founder of the *Bible Christian Methodists*; they are sometimes called Bryanites. They were not seceders from the Wesleyan stock, but an independent sect, that gradually adopted the Wesleyan tenets. In 1852 they had 403 chapels, 113 itinerant ministers, 1059 local preachers, and 13,862 members. The *Primitive Methodists*, who are sometimes known as Ranters, originated in Staffordshire: their professed object is to recall the Wesleyans to the ancient spirit and fervour with which their fathers met rude and uncivilised mobs. By the census return the attendance on March 31, 1851, was, in the morning, 98,001; afternoon, 172,684; evening, 229,646; and in 1853, the return gave 1789 chapels. By their own report, of June 1860, they have 2267 chapels, and 3268 rented chapels and rooms, 675 travelling preachers, and 132,114 members in society. They have also 167,533 Sunday scholars, with 30,988 teachers. The report claims a considerable extension of the sect in every branch. Dissension in Leeds, in 1829, gave birth to the *Protestant Methodists*, who declared that the Wesleyans had violated their own laws by the erection of an organ in one of the chapels in that town, contrary to the decision of a leaders' meeting. In 1835, the establishment of the Theological Institution, the expulsion of Dr. Samuel Warren, and contentions on the rights of leaders' meetings, gave existence to the *Association Methodists*. In 1852 the Association had 329 chapels, and 171 rooms and other places for preaching, 90 itinerant ministers, 1016 local preachers, 1353 class leaders, and 19,411 members. Attendance on Census Sunday: morning, 32,308; afternoon, 21,140; evening, 40,565.

The *Wesleyan Reformers* separated formally in March, 1850, in consequence of the expulsion, by the Conference, of certain ministers, accused only of anonymous writings against the powers claimed by the Conference. At a meeting of delegates, in the month named,

resolutions were passed, declaring that they approved of and adhered to the doctrines of John Wesley; and that they denied the right on any just or scriptural ground of the Conference to assume to be the sole legislative body. They also resolved that leaders and office-bearers should be chosen by the church; that admission into and expulsion from the church, and all disciplinary acts, should be determined by a leaders' meeting, subject to an appeal to the quarterly meeting; that the quarterly meeting should consist of all the travelling and local teachers, leaders, trustees, and stewards of the society; that the district meetings should consist of the travelling preachers of the district and of an equal number of lay representatives, to be chosen at the March quarterly meetings; and that the Connectional Committees should consist equally of preachers and lay members of the society. This secession it was estimated drew off 100,000 members from the parent stock; but a large body of the reformers having joined the Wesleyan Association in forming the United Methodist Free Church, the *Reform Union* numbers only about 60,000, with upwards of 3000 places of worship, about 3000 preachers, and 500 class-leaders. The attendance on Census Sunday, 1851, was—morning, 30,470; afternoon, 16,080; evening, 44,953. The report of the eleventh delegate meeting, held in October, 1859, states that there were then in the Union, 261 chapels, 186 preaching places, 873 preachers, and 118 on trial, 27 ministers, 1056 leaders, 17,088 members, and 1178 on trial, and 31,693 scholars.

The report of the third annual meeting of the *United Methodist Free Church*, held in July and August, 1859, states that in their Connexion there are 825 chapels, 422 preaching places, 163 itinerant preachers, 2522 local preachers, 2095 leaders, 50,133 members, and 3799 on trial, and 97,961 Sunday scholars.

(Reports of the Annual Conferences of the various sects, and the report of the registrar-general on *Religious Worship* after the Census of 1851, published in 1853.)

METHOL. A hydrocarbon constituent of wood naphtha. It is lighter than water, boils at 347° Fahr., and smells like spirit of turpentine.

METHYL; METHYLO; METHO. Prefixes used in chemical nomenclature to denote the presence of the radical methyl in the compounds to which they are applied. Thus methylconine signifies conine in which hydrogen is replaced by methyl. Such bodies, when of sufficient importance, will be found described under the name before which the prefix is placed, thus *methyl-urea* will be found under **UREA**, &c.

METHYL $\left(\begin{smallmatrix} C_2H_3 \\ C_2H_3 \end{smallmatrix} \right)$. An organic radical, homologous with **ETHYL**.

It is the lowest term in the series $C_n H_{n+1}$. Like ethyl it forms a very numerous class of compounds, but they have not been so completely investigated as those of the latter radical.

Methyl is obtained by acting upon iodide of methyl with zinc, in precisely the same way as described under the preparation of **ETHYL**.

Methyl is a colourless gas, of specific gravity 1.0365. It burns with a bluish, scarcely luminous flame, is almost insoluble in water, and only slightly so in alcohol. It is colourless and tasteless, and is not liquefied at a temperature of 0° Fahr. Neither concentrated sulphuric acid, fuming nitric acid, nor caustic potash, act upon it. It does not combine directly with oxygen, sulphur, or iodine, nor in the dark with chlorine; but when two volumes of the latter gas and one of methyl are exposed to diffused daylight, a mixture of hydrochloric acid gas and *monochlor-methyl* (C_2H_2Cl) is produced, no condensation occurring.

Hydride of methyl ($C_2H_4 = C_2H_3, H$). *Light carburetted hydrogen*; *Subcarburetted hydrogen*; *Formen*; *Marsh-gas*, or *Fire-damp*.

The last two are the names for this gas in its best known form. It sometimes issues, for months together, from a fissure in a coal seam, rushing forth as if escaping from under high pressure. "Blowers" is the name given by the miners to these natural discharges of fire-damp. They are sometimes so numerous in a mine that it could not be safely worked were it not for the use of the safety-lamp, discovered by Sir H. Davy. [**LAMP, SAFETY.**] By its means the miner is enabled to work in atmospheres that would be set fire to were his source of light a naked flame.

Hydride of methyl is also one of the gaseous exhalations from marshes and stagnant pools, and hence the name of *marsh-gas*. The bubbles of gas that rise to the surface when the mud at the bottom of a pond is stirred with a stick consist chiefly of marsh gas.

Hydride of methyl may be artificially prepared by strongly heating a mixture of four parts of crystallised acetate of soda, four of solid hydrate of potash, and six of powdered quicklime.

Hydride of methyl is colourless, inodorous, tasteless, and insoluble in water. Specific gravity 0.5596. Air containing a large per-centage of it may be inhaled, for almost any length of time, without producing the slightest apparent injury. It is inflammable, burning with a yellow, somewhat feebly luminous flame, the products of combustion being carbonic acid and water. For this combustion twice its bulk, or two volumes, of oxygen are necessary, one volume of carbonic and two of steam resulting. Inasmuch, however, as this oxygen is, in the case of colliery explosions, obtained from the air, and as moreover air only contains one-fifth of its bulk of oxygen (the remaining four-fifths being

nitrogen, which alone cannot support life), it follows that the burning of fire-damp is immediately attended with the complete spoliation of ten times its bulk of air, the production of an equal quantity of suffocating gas, and the consequent vitiation of the whole atmosphere in the neighbourhood. The effect of such a state of things is, unhappily, only too well known to the miner, who fears the *after-damp*, or *choke-damp* as he calls it, perhaps more than he does the explosion itself.

Oxide of methyl (C_2H_3O, C_2H_3O). *Methylic ether*. This body corresponds to the ordinary ether, or correctly speaking ethylic ether, of the **ETHYL** series of compounds. It is also produced in a similar manner, namely, by submitting to distillation a mixture of methylic alcohol and sulphuric acid. Unlike ethylic ether, however, methylic ether is at ordinary temperatures a permanent gas. When cooled to 65° below the freezing point of water, by means of a mixture of snow and chloride of calcium, it condenses to a liquid, the boiling point of which is - 6° Fahr. (Berthollet). Its specific gravity is 1.617. It is inflammable, burning with a pale flame, is soluble in water to the extent of thirty-seven times its bulk, and still more soluble in alcohol. It is colourless, has an oppressive ethereal odour and pungent taste, properties also possessed by its solutions. From its formula it will be observed that methylic ether is isomeric with common alcohol; in vapour-density the two are also identical. Methylic ether dissolves in strong sulphuric acid, but is again evolved on dilution. Anhydrous sulphuric acid combines with it, and forms sulphate of methyl.

Oxide of methyl, like oxide of ethyl, combines with acids to form a class of ethereal salts, much resembling those described under **ETHYL**. They are also, for the most part, prepared in the same way. The following are the formulæ of a few of the principal ones: details concerning them will be found in the articles on the respective acids, under the name of *methylic derivatives* of the acid:—

Acetate of methyl (methyl-acetic ether)	. . . $C_2H_3O, C_4H_5O_2$
Benzoate of methyl (methyl-benzoic ether)	. . . $C_2H_3O, C_{14}H_5O_2$
Borate of methyl (methyl-boracic ether)	. . . $3C_2H_3O, BO_3$
Butyrate of methyl (methyl-butyric ether)	. . . $C_2H_3O, C_8H_7O_2$
Cyanate of methyl (methyl-cyanic ether)	. . . C_2H_3O, C_2NO
Cyanurate of methyl (methyl-cyanuric ether)	. . . $3C_2H_3O, C_6N_3O_3$
Formiate of methyl (methyl-formic ether)	. . . C_2H_3O, C_2HO_2
Hyponitrite of methyl (methyl-nitrous ether)	. . . $C_2H_3O, NO_2^?$
Nitrate of methyl (methyl-nitric ether)	. . . C_2H_3O, NO_5
Oxalate of methyl (methyl-oxalic ether)	. . . $2C_2H_3O, C_4O_6$
Salicylate of methyl (methyl-salicylic ether)	. . . $C_2H_3O, C_{14}H_5O_2$
Sulphamate of methyl (sulphamethylane)	. . . $C_2H_3O, NH_2(SO_2)O_3$
Sulphate of methyl (methyl-sulphuric ether)	. . . C_2H_3O, SO_3
Valerate of methyl (methyl-valeric ether)	. . . $C_2H_3O, C_{10}H_9O_2$

Butyrate of methyl has an odour resembling that of the rennet apple. Oxalate of methyl is solid at ordinary temperatures. Salicylate of methyl is identical with oil of wintergreen. [**ESSENTIAL OILS.**]

Chlorine derivatives of oxide of methyl. Chlorine acts upon methylic ether, and successively removes and replaces one, two, and three equivalents of hydrogen; mono-, bi-, and per-chlorinated bodies being formed ($C_2H_2ClO : C_2HCl_2O : C_2Cl_3O$).

Hydrated oxide of methyl (C_2H_3O, HO). *Methylic alcohol*; *Wood spirit*; *Pyroxylic spirit*. This liquid is a strict homologue of vinic alcohol. Its source is the aqueous portion of the volatile products of the destructive distillation of wood. [**CHARCOAL; ACETIC ACID.**] After rectification from lime it is sent into commerce under the name of *wood naphtha*. The latter liquid, however, in addition to methylic alcohol, contains acetate of methyl and some oily hydrocarbons. To purify it from the acetate it is rectified from caustic soda, and the distillate having been digested with chloride of calcium (which combines with the methylic alcohol and forms a non-volatile salt), the hydrocarbons are got rid of by a second distillation, at a heat of 212°; water being now added to the salt, decomposition takes place, and the aqueous methylic alcohol separated by distillation is finally obtained pure and anhydrous on being re-rectified from lime.

Hydrate of methyl is a colourless liquid, of specific gravity 0.798 at 69° Fahr. It has an unpleasant burning taste, and an empyreumatic odour. When absolutely pure, however, its odour is rather agreeable than otherwise. It is readily soluble in water, alcohol, or ether. It burns with a pale flame, resembling that of alcohol. Its boiling point is 142° Fahr. When pure it gives no cloudiness on mixing with water, nor does it give a black precipitate of metallic mercury when added to a solution of mercurous nitrate. It dissolves the solid alkalis, but is immediately coloured brown by them, a reaction that distinguishes it from ethylic alcohol, which is not so coloured until after the lapse of considerable time.

The chief use of crude woodspirit in the arts is for dissolving shellac, and other resins, the solutions thus formed being largely used in **HAT MANUFACTURE**. For this and other purposes, however, *methylated spirit* is now commonly used; it is a mixture of spirit of wine of fifty per cent. over-proof, with one-ninth of its bulk of woodspirit.

The strength of woodspirit may be conveniently estimated by a hydrometer. The annexed table, by Deville, shows what per-centage

of anhydrous methylic alcohol is contained in woodspirit of given specific gravity, at a temperature of 48.2° Fahr. :—

Sp. gr.	Wood spirit in 100 parts.	Sp. gr.	Wood spirit in 100 parts.
0.8070	100	0.9429	40
0.8371	90	0.9576	30
0.8619	80	0.9709	20
0.8873	70	0.9751	10
0.9072	60	0.9857	5
0.9232	50		

Heated with potash-lime, methylic alcohol is converted into formiate of potash, with disengagement of hydrogen. Oxidising agents also give formic acid, and sometimes an intermediate body resembling an aldehyde. Malaguti calls this body *methylal* ($C_2H_5O_2$), and shows that the *formo-methylal* of M. Dumas is a mixture of methylal and formiate of methyl. When potassium is added to methylic alcohol, hydrogen is evolved, and *methylate of potash* (C_2H_5O, KO), corresponding to the ethylate of the same base, is formed.

Sulphides of methyl. In composition, properties, and mode of formation, these bodies closely resemble the corresponding ETHYL compounds. Methyl-mercaptan (C_2H_5S, HS) boils at 69.8° Fahr.; sulphide of methyl (C_2H_5S, C_2H_5S) at 105.8°; and bisulphide of methyl ($C_2H_5S_2, C_2H_5S_2$) at about 242°. There also appears to exist a tersulphide of methyl ($C_2H_5S_3, C_2H_5S_3$).

Chloride of methyl (C_2H_5Cl).—This is produced from wood spirit in the same way that chloride of ethyl is obtained from spirit of wine. At ordinary temperature it is a colourless gas, of ethereal odour and sweet taste, specific gravity 1.736. When cooled to -33° Fahr., it condenses to a liquid, the boiling point of which is about -6° Fahr. By the prolonged action of a dilute solution of potash upon chloride of methyl Berthollet has obtained methylic alcohol, and as chloride of methyl results from the action of chlorine on hydride of methyl, and hydride of methyl may be directly obtained from its elements, it follows that wood spirit, like most of the other alcohols, may be produced artificially.

By the action of chlorine upon chloride of methyl there are successively produced *chloride of chlormethyl* (C_2H_4Cl, Cl), *chloride of bichlormethyl* (chloroform) (C_2HCl_2, Cl), and *chloride of perchlormethyl* (C_2Cl_3, Cl). The latter is identical with bichloride of carbon. *Chloride of nitro-perchlormethyl* ($C_2Cl_3(NO_2), Cl$) is CHLOROPICRINE.

Bromide of methyl (C_2H_5Br) is made by a similar method to bromide of ETHYL. Its specific gravity is 1.664; boiling point about 55° Fahr. *Bromide of bibrom-methyl* (C_2HBr_2, Br), or bromoform, is produced by the simultaneous action of caustic potash and bromine upon woodspirit, alcohol, or acetone. The *bromide of nitro-perbrom-methyl* ($C_2Br_2(NO_2), Br$) is bromopicrine.

Iodide of methyl (C_2H_5I) is made in the same way as, and much resembles, iodide of ethyl. Its specific gravity at 72° Fahr. is 2.237. Boiling point between 105° and 120°. From iodide of methyl there are obtained by substitution processes the following compounds:—*Iodide of bichlormethyl* (C_2HCl_2, I) or CHLORIDOFORM; *Iodide of bibrom-methyl* (C_2HBr_2, I), or BROMIDOFORM; *Iodide of bi-iod-methyl* (C_2HI_2, I), or IODOFORM. By distilling iodoform with sulphide of mercury, Boucharlat has obtained an oily body which he calls *sulphoform*, but it has not yet been thoroughly investigated. A *cyanide of bi-iod-methyl* (C_2HI_2, Cy) has also been described.

Nitriles of methyl. [ORGANIC BASES.]

Cyanide of methyl (C_2H_5Cy), *Acetonitrile* or *acetonitril*.—Prepared by distillation, from a mixture of sulphomethylate of potash and cyanide of potassium. Boiling point 170.6° Fahr. *Cyanide of tri-chlormethyl* (C_2Cl_3Cy) is identical with *chloracetonitrile*.

Carbonate of methyl ($2C_2H_5O, C_2O_4$) has not been prepared, but *methylcarbonic acid* or *carbomethylic acid* (C_2H_5O, HO, C_2O_4) in the state of a baryta salt (C_2H_5O, BaO, C_2O_4) is precipitated when carbonic acid is passed through a solution of baryta in wood spirit.

Metallic methides.—This series of bodies is not quite so complete as the corresponding series of *ethides*. [ETHYL.] They are in nearly all cases produced by methods similar to those for obtaining the respective metallic ethides. For a description of them, see ORGANO-METALLIC BODIES.

Methyl-hexyl ($C_{14}H_{30} = C_2H_5, C_{12}H_{25}$) *Methylide of hexyl*.—This is a double alcohol radicle, containing methyl, united with hexyl—the radical of CAPROIC ALCOHOL. Its boiling point is 179.6° (?) Fahr., and its vapour density 3.426.

Methylene (C_2H_2) is a gaseous body, obtained on passing chloride of methyl through a red-hot porcelain tube, hydrochloric acid being produced at the same time. It cannot, like ethylene, be formed by the action of hot concentrated sulphuric acid on the alcohol.

The following are the names and formulæ of the remaining more important compounds of methyl. Those containing nitrogen will be described in detail under ORGANIC BASES.

Methylamine	N	$\begin{Bmatrix} C_2H_5 \\ H \\ H \end{Bmatrix}$
Dimethylamine	N	$\begin{Bmatrix} C_2H_5 \\ C_2H_5 \\ H \end{Bmatrix}$

Trimethylamine	N	$\begin{Bmatrix} C_2H_5 \\ C_2H_5 \\ C_2H_5 \end{Bmatrix}$
Tetramethylammonium, hyd. ox.	N	$\begin{Bmatrix} C_2H_5 \\ C_2H_5 \\ C_2H_5 \\ C_2H_5 \end{Bmatrix} O, HO$

Trimethylphosphine	P	$\begin{Bmatrix} C_2H_5 \\ C_2H_5 \\ C_2H_5 \end{Bmatrix}$

------------------------------	--	------------------------

Methylxanthic acid (methyldisulphocarbonic acid).		
---	--	--

METHYLCAMPHORIC ACID. [CAMPHOR; *Camphomethylic Acid*.]

METHYL-CONINE. [CONINE.]

METHYL-HEXYL. [METHYL.]

METHYL-PHENIDINE. [ANISIDINE.]

METHYL-UREA. [UREA.]

METHYLAL ($C_2H_5O_2$). One of the products of the oxidation of methylic alcohol. It contains the elements of 3 atoms of methylic alcohol minus 4 atoms of water.

METHYLAMINE. [ORGANIC BASES.]

METHYLATED SPIRIT. A mixture of alcohol with 10 per cent. of wood naphtha, allowed by the Excise to be sold duty free for manufacturing purposes. [ALCOHOL.]

METHYLENE. [METHYL.]

METOLUIDINE ($C_{14}H_5CyN$). A cyanogen derivative of toluidine. [ORGANIC BASES.]

METONIC CYCLE. [METON, in BIOG. DIV.]

METOPE. [ALTO RELIEVO.]

METRE (from the Greek μέτρον, a measure) is that quality of verse by which it is to the ear distinguishable from prose. It is frequently

held to be one of the essentials of poetry; imaginative thought being the other. No reason can be assigned for this opinion, the truth being that it is attributable only to our nature as men, by which we feel pleasure in rhythmical arrangement of words, and consistently with which we cannot consider imaginative writing as perfect, unless couched in metre.

A distinction has been drawn between ancient and modern metres, one being said to depend on quantity, the other on accent; quantity and accent being further supposed to differ in kind. A little reflection however will tend to convince us that delicacy of ear has as much to do with the difference between ancient and modern metres as any fancied change from quantity into accent.

The southern nations still retain this delicacy of ear, as we know from the marked difference in Italian between the pronunciation of double and single consonants, a difference to which our language is a stranger as far as *time* is concerned. Though we see no distinction in time between the second syllable of the words *laborare* and *liberare*, there is no reason why the Romans should not; and with that assumption the whole difference between accent and quantity vanishes. It would be useless to enumerate the names which have been given to metres. The Greek and Roman metres differ from our own in being more numerous, and in allowing collocations of syllables (called feet) such as we could scarcely feel to be consonant with rhythm. The cause of this difference seems to lie in the form of each language.

Another grand distinction between ancient and modern metres is that of rhyme, which occurs but seldom in the former, and which, until the time of Shakspeare, was nearly universal in the latter. Ancient and modern languages both afford specimens of the alliterative measure. [ALLITERATION.] Those who seek for further information on the subject of English metres, particularly on peculiarities which have occasioned so much difficulty to the readers of Chaucer, will do well to consult Mr. Guest's 'History of English Metres.' Some observations by Coleridge, prefixed to 'Christabel,' are also worth attention.

METRONOME (from *μέτρον*, a measure, and *νόμος*, a division; also, a song), an ingenious instrument; a pendulum, the point of suspension of which is between the extremities, invented and introduced about the year 1814 by John Maelzel (civil engineer, and mechanician to the emperor of Austria), for the purpose of determining the movement—that is, the quickness or slowness—of musical compositions.

Of the utility of a *time-measurer*, both to composers and performers, and for some account of its early use, see CHRONOMETER.

Of Maelzel's Metronome there are two kinds. The one is a pendulum kept in motion by a spring and wheelwork, and which ticks the vibrations:—the other is also a pendulum, as above described, but without any machinery, and acting so long as the force of the impulse given shall last. The former, therefore, it will be obvious, is complicated and expensive; the latter is simple and cheap.

The inventor thus describes and explains the manner of using this instrument:—

"1. A sliding weight is attached to the rod (which is graduated) or steel pendulum; the higher up this weight is shifted, the slower will be the vibrations; and *vice versa*; so that when the weight corresponds with the number 50, the vibrations will be the slowest possible; at No. 160 they will be the quickest.

"2. These numbers have all reference to a *minute of time*; that is, when the weight is placed at 50, fifty beats or ticks will occur in each minute; when at 60, 60 beats, or seconds exactly, in a minute; when at 100, 100 beats in a minute, &c.; any stop-watch, therefore, will show how far the correctness of the metronome may be depended on.

"3. The doubles of the numbers of the scale answer to a precisely *double* degree of velocity. Thus, if 50 be the proper number for a minim, 100 will be the number for the crotchet in the same movement, &c. The numbers omitted on the scale have been found practically unnecessary.

"4. The composer is best able to judge, from the nature of his movement, whether to mark its time by minims, crotchets, quavers, &c. Generally speaking it will be found, that in *adagios*, it is most convenient to mark the time on the Metronome by quavers; in *andantes* by crotchets; in *allegros* by minims, and in *prestos* by whole bars. As often however as the case may admit, it is desirable that the pendulum should be made to beat integral parts of a bar, just as a master would beat or count the time."

Much opposition was made to the use of this excellent instrument, when first introduced; but no sensible composer or performer now entertains a doubt of the usefulness of the Metronome, or of some kind of pendulum answering the same purpose.

METROPOLIS. [COLONY.]

METROPOLITAN. [ARCHBISHOP.]

MEXICAN ARCHITECTURE. The ancient architectural remains in the Valley of Mexico, and in the adjacent countries, have never yet been examined with sufficient care and patience by a competent architect, or archaeologist, to enable us to speak with any approach to certainty of their relative antiquity, or to characterise distinctly their essential peculiarities of age and style. Those who have visited and described them have been, for the most part, chiefly interested in discovering points of resemblance or dissimilitude with other ancient

edifices, as those of Egypt, India, Greece, or even, as in the case of Lord Kingsborough, Jerusalem. Mexican architecture is that of two distinct people: the Toltecs, who occupied Mexico prior to the 7th century of our era; and the Aztecs, with whom may be associated the Chichemacas, who inhabited the country at the Spanish conquest early in the 16th century. That which is believed to belong to the earlier race is also the most remarkable; the later would seem to have been derived from it. Architecture in its essential features similar to that of the Toltecs exists in various parts of Central America, and may be associated with it. As far as our present knowledge extends, the architecture of Mexico is to be regarded as, in the main, self-developed, rather than borrowed from that of any other country. The buildings display vast labour, and often considerable skill; but, whether regarded as constructive works or as works of art, they are at best the productions of a barbarous people. Yet, in their way, they are works of singular interest, and will repay a far more thorough investigation than they have yet received.

As in almost every other national architecture, the most important edifices are those devoted to the purposes of religion. These are known as Teocallis, and appear, like the Egyptian temples, to have contained apartments for the priests; they also contained sepulchral chambers, and had descending galleries leading down into caverned recesses or halls, which are variously conjectured to have been used for religious mysteries, or as places for the concealment of treasures, but may probably have been used for both purposes. In plan, these buildings are square; in form pyramidal, generally rising in successive storeys or stages, like a series of truncated pyramids placed one above another, each successive one being smaller than the one on which it immediately rests, so that it stands upon a platform or terrace; the holy place, or temple proper, being built on the summit, and subordinate in effect to the pyramid. The sides of the pyramids face the cardinal points; their angle of inclination is seldom less than 70 degrees, which differs little from that of the pyramids of Egypt.

The largest, most sacred, and best known of these Teocallis is that of Cholula, for which a fancied prototype has been found in the Temple of Belus, as described by Herodotus. This pyramid-temple of Cholula is now in appearance little more than a vast mound of earth covered with vegetation, and crowned with a small church. But on near inspection its architectural features are sufficiently distinguishable. The base of this huge structure measures 1440 feet each way (some authorities say 1488 feet); its height is 177 feet: the sides of the base of the great pyramid of Gizeh are only 763 feet, so that the area of the Mexican pyramid is nearly four times that of the greatest of those of Egypt, but it is not a third of the height. The body of the pyramid is formed of clay and sun-dried bricks. It consists of four terraces; and on the summit is a small church dedicated to the Virgin, which occupies a temple of the Toltek god of the air. From the perishable material of which it was constructed, its decorative features have all disappeared, and but a very imperfect notion can be formed of its original appearance. It contains spacious sepulchral cavities; and a square chamber formed of stone and supported by beams of cypress wood was some years back discovered in it. Within this chamber were two skeletons and several painted vases.

The buildings outside the limits of the valley of Mexico, and especially those in Central America, are in far better preservation. One of the most stupendous monuments of this style of architecture occurs at Palenque, near the eastern extremity of the present republic of Mexico. The great Teocalli at Palenque (built, according to the startling assumption of Lord Kingsborough, after the model of the temple of Solomon) comprised within its extensive precincts various sanctuaries and sepulchres, courts and cloisters, subterranean galleries, and cells for the habitation of the priests. The whole rests on a platform, composed of three graduated terraces, and forms a spacious quadrangle inclosed by porticoes. On each side of the exterior is an ascent or flight of stairs, and on the east a second flight leading down, after the first is ascended, into the cloistered court. Beneath the cloisters are what are conjectured to have been initiatory galleries; and in the centre of the quadrangle is what appears to be the ruins of an altar or "high place." The temple itself is oblong in plan, 76 feet wide by 26 feet deep, and is decorated with sculpture and hieroglyphics executed in stucco. The roof is formed by graduated courses of stone, which meet at the summit, and has six ornamental projections, placed above the openings formed by the supporting piers, which were probably intended to support small idols or ornamental figures. The city of Palenque itself exhibits a variety of buildings, temples, palaces, baths, and private houses, all manifesting excellence of workmanship combined with considerable skill in design.

The palaces, or houses of the kings, appear to have resembled the temples in being based on pyramidal substructures; but these are generally oblong instead of square in plan, and much lower than the temple-pyramids. Their substructure is usually of stone, and very massive, elaborately sculptured with figures of idols and masks of monstrous proportions, scrolls, mat-work, &c., often executed with great skill. The upper part appears to have been of wood, but has mostly perished. One of the most characteristic of these is the palace at Mitla, the remains of which show that it must have been an edifice of great extent and grandeur. It appears to have originally comprised five distinct portions, which have been regarded as places of retirement

for the kings, or as tombs. Three of these still remain. The principal one is nearly 130 feet long. A staircase leads to a subterranean apartment 88 feet by 26, the walls of which, like the exterior, appear to have been sculptured or tooled, in imitation of mat or basket-work—a species of decoration characteristic of Toltec taste, and often found in sepulchral chambers. This same building has also a spacious hall supported by six plain cylindrical columns of porphyry, without base or capital, and in some respects differing from any found elsewhere. The ceiling which they support is formed of beams and slabs of cypress or savin wood of large size. Over the principal entrance is a stone lintel 12 feet long and 3 feet deep. There is no appearance of windows. The interiors of the chambers have been elaborately painted with representations of sacrifices, trophies, weapons, &c.; and with ornaments resembling those found in Etruscan decorations. Other palaces, especially those in Central America, that at Zayi for instance, have the terraces presenting successive architectural façades instead of mere flights of steps. Some instances, as the Casa de las Monjas, at Uxmas, occur where the buildings have been arranged around a central courtyard.

At Teotihuacan, about 8 leagues to the north-east of the city of Mexico, are several hundred small pyramids, ranged in files or lines, and two larger ones, which are believed to have been consecrated to the sun and moon. Each of the latter is divided into four platforms, the slopes between which consisted of steps, and on the summit was a colossal stone statue covered with plates of gold, which were stripped off by Cortes's soldiers, and the statues themselves destroyed.

Besides monuments which are chiefly works of magnificence, others exist which attest the high degree of civilisation attained by the Toltecs, such as roads and bridges. The former of these were constructed of huge blocks of stone, and frequently carried on a continued level, so as to be viaducts across valleys. There are also throughout Central America numerous excavations or rock-hewn halls and caverns, called by the natives "granaries of the giants." They resemble the Pelasgic fabric near Argos known by the name of the Treasury of Atreus, are generally dome-shaped, and the central apartment is lighted through an aperture in its vault. Other points of resemblance to Pelasgic masonry may be found in the doorways to these subterranean galleries and apartments, which are to some extent similar to the gate of Mycenæ; and also in the peculiar triangular arch formed by courses of stones projecting over each other. Arches of this mode of construction are found in the cloisters of the building at Palenque. There are also extensive works for defensive purposes, earthen sepulchral mounds, &c. The remains of sculpture found in Mexico are numerous, and of great variety both of form and material.

(Lord Kingsborough, *Antiquities of Mexico*; Stephens, *Central America*, and *Yucatan*; Catherwood, *Ancient Monuments, Central America*; Fergusson, *Handbook of Architecture*, vol. i.; Gailhabaud, *Monuments Anciens et Modernes*, tom. iv.)

MEZEREUM, OR DAPHNE MEZEREUM, Spurge-olive, is an indigenous shrub; the bark obtained, in spring, from the root, is officinal. It is covered by a thin epidermis, green within, brown without. It is destitute of smell, but has a very acrid pungent taste, lasting for hours, and causes vesications. Its virulence even amounts to a poisonous degree, but is said to be lessened by camphor.

In the 'London Pharmacopœia' it only enters as an ingredient into the decoction sarsap. comp. It consists of an acrid resin, and an acrid volatile oil, and daphnin, which is not active. [MEZEREON, in NAT. HIST. DIV.]

The bark yields its properties to water, and still more perfectly to vinegar. The simple decoction of the 'Edinburgh Pharmacopœia' certainly possesses considerable power. Mezereon in a small dose acts upon the secretions of the salivary glands, the mucous membranes, the kidneys, and the skin. It also rouses the nervous energy of the brain, as its action in many cases of coma and stupor proves.

It may be employed locally to stimulate the salivary glands, or to remove paralysis of the mouth or throat; when so employed it is to be chewed, but the saliva must not be swallowed, as its acrimony causes inflammation of the stomach and intestines; and this may even be fatal from the hæmorrhage, vomiting, and purging which attend it. The berries swallowed incautiously produce the same bad effects.

The simple decoction, along with carbonate of ammonia, given in proper doses every two or four hours, has in several instances rescued patients from a state of imminent danger in the stage of collapse of typhus fever, or that of coma and effusion at the base of the brain, which sometimes occurs in scarlet fever. In torpor of the brain, in leuco-phlegmatic subjects, and in approaching amaurosis, it is also of use. It has also been found serviceable in chronic rheumatism and chronic cutaneous diseases. A portion of the bark macerated in vinegar and applied to the skin, forms a powerful vesicant. [DAPHNE, in NAT. HIST. DIV.]

MEZZANINE (Italian, *Mezzanini*), in architecture, a low storey between two higher ones: the same as ENTRESOL.

MEZZOTINTO, in engraving, a peculiar mode of engraving designs of any description upon plates of copper or steel, with the view of obtaining impressions therefrom. In this style of engraving, which essentially differs from every other, the surface of the plate is first indented or hacked all over by the action of an instrument something like a chisel, with a toothed or serrated edge, called a *cradle*, or *mezzo-*

tinto *grounder*. This tool being rocked to and fro in many directions, indents or bars the plate uniformly over its face, and produces what is called the mezzotinto grain or ground.

The barb, or nap, thus produced retains the printing ink; and if in this state of preparation an impression were taken from the plate upon paper, it would be uniformly of a deep black colour.

The directions, or *ways*, as they are technically called, given to the grounding-tool, are determined by a regulated plan, and for this purpose an ingenious sort of scale is used which enables the workman to pass over the plate in almost any number of directions without repeating any one of them. The mezzotinto ground being thus laid, it is at this period that the business of the artist properly commences. Having traced or drawn, with a pencil or other instrument, his outline upon the paper (unless indeed, as is sometimes the case, this should have been etched by the ordinary process, previous to the mezzotint ground having been laid), he proceeds to remove the nap or ground, in conformity with the design, from all those parts which are not intended to be perfectly black in the impression. The instruments required for this purpose are scrapers and burnishers; with the former he scrapes away more and more of the ground in proportion to the brightness of the light, and the burnishers are used to produce perfect whiteness where it is required, as the high lights on the forehead or tip of the nose, or white linen in a portrait, &c. As the work proceeds it may be blackened with ink, applied with a printer's ball or otherwise, to ascertain the effect; after which the scraping may again be proceeded with, the artist taking care always to commence where the strongest lights are intended to appear.

The great facility with which mezzotintos are executed, as compared with line-engravings, will be obvious, seeing that it is much easier to scrape or burnish away parts of a dark ground corresponding with any design sketched upon it, than it is to form shades upon a white ground by an infinite number of strokes, hatches, or points, made with the *graver* or *etching-needle*. Herein consists the leading difference between this and all other modes of engraving; for while the process in each of these is invariably from *light to dark*, in mezzotinto it is from *dark to light*; and even the very deepest shades are produced, as we have seen, before the design is commenced. The characteristic or distinguishing excellence of mezzotinto engraving would seem to consist in the richness, depth, mellowness, and harmony of its shadows, the obscurity of which especially sympathises with fine effects of chiaroscuro.

Having mentioned what we conceive to be the characteristic excellence of mezzotinto, namely, the richness and profundity of its shadows, it is but fair to add that its chief defect seems to be a corresponding poverty in the lights; and this objection will be felt to have much weight, when it is considered that it is to the lights in a picture that the eye is invariably attracted. On the lights therefore the line-engraver displays all that delicacy and beauty of line which agreeably irritates the eye and compensates for the absence of colour, by rendering the lights more interesting than the shadows. The lights in mezzotinto, on the contrary, where they occur in broad masses, have been ever felt by the judicious to be comparatively cold and poor. This objection has been partly obviated by a judicious admixture of *etching* with the mezzotinto, which, by enriching the lights, has done much towards uniting the energies of both styles. Objection has also been taken to mezzotinto on account of the limited number of good impressions which an engraving in this style would yield, in consequence of the very superficial nature of the ground. A work of this sort, however, was always more susceptible of renovation by retouching than one produced by any of the other modes; and the introduction of steel plates, which are now commonly substituted for those of copper, has removed the objection almost entirely, a very large number of good impressions being thus ensured without the necessity of retouching. A copper-plate will seldom furnish above one hundred and fifty good prints before requiring retouching. When the plate begins to wear, the practice is to work it over again, partially, with the cradle, and afterwards to again have recourse to the scrapers; and in this way impressions of fifty at a time may be taken; so that by alternately retouching and printing by fifties, five hundred prints are frequently obtained from one copper-plate. But from a steel-plate eight or ten times that number may be obtained. The process is the same in the one case as in the other, but heavier pressure on the grounding-tool is requisite on a steel-plate. A greater number of *ways* also is desirable, and these may be effected without rendering the subsequent engraving liable to more rapid deterioration, as would be the case upon copper. As many as ninety *ways* are frequently used on steel, while the number on a copper-plate varies from twenty-four to forty, which latter is rarely exceeded.

The discovery of the art of engraving in mezzotinto has been a subject of some controversy. The account commonly given of its discovery is, that Prince Rupert observed one morning a soldier engaged in cleaning from his musket the rust which the night-dew had occasioned, and perceiving upon it, as he thought, some resemblance to a figure, it occurred to him whether or not, by corroding or grounding a plate all over in a manner resembling the rust, he might not afterwards scrape away a design upon it, from which impressions might be obtained. He tried, it is said, and succeeded, and thus became the inventor of mezzotinto engraving. The merit of the discovery

was claimed in the 'Parentalia,' p. 214, for Sir Christopher Wren, on the ground of a communication which he made to the Royal Society in 1662, the Journals of which society for October in that year record that "Doctor Wren presented some cuts, done by himself in a new way, whereby he could almost as soon do a subject upon a plate of brass or copper as another could draw it with a crayon upon paper." This claim is however disposed of by the fact that the principal mezzotinto by Prince Rupert, the 'Decollation of St. John the Baptist,' after a design by Spagnoletto, bears date 1658, which is four years earlier than Sir Christopher Wren's communication to the Royal Society; whilst Evelyn's 'Sculptura' (8vo, 1662), in which Rupert's "invention" is described and illustrated by an engraving executed by the prince, was presented to the Royal Society at the meeting of the 11th of June, 1662, or four months prior to Wren's communication. (Weld, 'Hist. of Royal Soc.,' i. 118.)

But while it is thus clear that the pretensions of Prince Rupert completely supersede those of Sir Christopher Wren, it is certain that those of Prince Rupert himself are invalid.

The real inventor of this art appears to have been Louis von Siegen (born 1609), a lieutenant-colonel in the service of the Landgrave of Hesse Cassel; and according to Baron Heneiken ('Idée Générale d'une Collection Complète d'Estampes,' 1771), Prince Rupert learnt the art from Von Siegen, whose first specimen made public was a portrait of the Princess Amelia-Elizabeth of Hesse. Proofs of this engraving of the first state bear the date 1642; of what is called the second state—of which there is a fine impression in the Print Room of the British Museum—the date is 1643, which is *fifteen years anterior* to the earliest of Prince Rupert's dates. In the same collection there are other prints by Von Siegen, one of which, if the external evidence were insufficient, would, we think, place the question beyond dispute; for, although without a date, it bears conclusive internal evidence of having been produced in the very infancy of the art, since it exhibits a total misconception or misapplication of its peculiar local powers, which, as we have said, are especially calculated for large masses of shadow of an indefinite character, such as a plain background to a portrait. The work to which we allude, which is a portrait of the Princess of Orange, the eldest daughter of Charles I., is a mixture of line-engraving and mezzotinto, and in it the background (which, if the mixed style be used, would be best effected by the mezzotint ground) is performed wholly in cross-hatches by the old process; while the flesh and even the hair, in which line-engraving might have been applied with advantage, are produced wholly by the new process of mezzotinto. Von Siegen's known mezzotinto plates are, we believe, in all only seven in number. There are also works by Theodore Caspar Fürstenburg, who probably learnt the art from Von Siegen, which bear date 1656, being earlier than anything by Prince Rupert; but the works both of Fürstenburg and Prince Rupert are engraved entirely by the newly discovered process of mezzotinto, and evince a more matured knowledge of its powers than those of its inventor Von Siegen. We will only further add the remarkable fact, that Von Siegen frequently attached the word "inventor" to his works, of which we subjoin an instance in the inscription to a 'Holy Family,' engraved by him after Carracci, and one of his latest performances: "Eminentissimo Principi Domino D. Julio Mazzarini, S.R.E., Cardinali, &c., novi hujus Sculpturæ modi *primus inventor* Ludovicus à Siegen humilissime offert, dicat et consecrat. A^o 1657."

It is not improbable, however, that Prince Rupert, by himself or with the assistance of Wallerant Vaillant, an artist whom he retained in his suite, may have improved the mechanical mode of laying the mezzotinto ground; and it should also be stated that there is by Sir Christopher Wren a head of a blackamoor, which is thought to have been done by a process differing from that of Prince Rupert. But these observations relate not to the principle of the art, but merely to the tool with which the *ground* is produced. The more perfect instrument at present used (that is, the *cradle*) is said by Bartsch to have been invented by Blooteling, a very skilful engraver in mezzotinto, who produced many of his works about 1672.

It is in our own country that mezzotinto engraving has been carried to the greatest perfection, and it attained excellence early in the last century. It was the favourite mode of Sir Joshua Reynolds, for whose style its painter-like breadth was singularly well fitted, and his patronage called forth a school of engravers who at once exhibited the full capabilities of the method. Nothing finer in their way can be desired than the long series of prints after Reynolds by James M'Ardell, Fisher, Dickinson, Richard Houston, Valentine Green, and the Watsons (Thomas, James, and Caroline); while, in a somewhat different way, Richard Earlom contributed more perhaps to the improvement and extension of this art than any one else, and whose works, embracing almost every class of subject (history, portrait, still life, &c.), are in almost every collection of importance in the country. The superiority thus acquired by the English mezzotinto engravers has been well maintained down to the present day, when, in Mr. Cousins, and others of scarcely less celebrity, we possess artists without equals among foreigners in this branch of art.

MIASMA is a Greek word (*μίασμα*) signifying pollution or corruption generally, and is employed to designate a certain volatile deleterious principle, arising either from the bodies of the sick, from animal or vegetable substances, or from the earth, and capable of exerting a

morbid influence on those exposed to its action. To the terrestrial emanations the Italians have given the name of malaria (from *mala* and *aria*, bad air), and this word has been generally adopted into other languages. To those emanations which arise from the bodies of the sick, the term contagion is more properly applied. In common parlance, then, miasma is seldom employed to designate the contagious effluvia of disease, but, with the adjunct marsh, is restricted to the sense in which malaria is used: hence we speak of marsh miasma and malaria as one and the same thing. Though marshes, whether salt or fresh, are prolific sources of malaria, they are by no means the only sources; the mud which is left by the drying of extensive ponds and lakes, the half-wet ditches of fortifications, and neglected sewers and drains, are capable of furnishing this poison. The decomposition of vegetable matter, in other circumstances than in connection with soil, is likewise capable of producing it; this has been exemplified in the sickness of ships from the leakage of sugar into a damp hold. Having enumerated some of the sources of miasma, the question naturally suggests itself,—What are the conditions essential to its development? The mere name of marsh miasma suggests the idea of stagnant water, and if the preceding enumeration of circumstances under which the production of malaria takes place be examined, it will be found that vegetable matter and moisture are present in all the examples, and that animal matter is so occasionally. But how great soever may be the share which moisture has in its production, it is certain that only a very small proportion is necessary. A marsh, the whole surface of which is thoroughly wet, is comparatively innocuous; but if partially or entirely dried by the summer's heat, it becomes extremely pestilential in autumn; indeed malaria, in its most intense degree, has been met with in low lands which had become as dry as a brick ground, with the vegetation utterly burnt up, and hence a high temperature seems to be another agent necessary, or at least favourable to its development. According to Dr. Ferguson, the only condition indispensable to the production of marsh miasma on all surfaces capable of absorption, is the paucity of water where it had previously recently abounded, a rule to which he assures us there is no exception in climates of high temperature. Of the chemical and physical properties of malaria nothing is known; even the very obvious question, whether it is always the same kind of poison, or whether a multiplicity of such poisons may not exist, is one which the present state of our knowledge does not enable us to answer. The occasional existence of putrefaction in conjunction with malaria is an accidental concomitant, but by no means essential to its activity as a poison. With regard to the effects of malaria, these manifest themselves in a longer or shorter period after exposure to its influence, and consist chiefly in the production of intermittent, remittent, and yellow fevers, dysentery, and typhus. The long-continued application of the same poison in a diluted form gives rise to various disorders of minor import, gradually undermines the constitution, and produces premature old age; even the inferior animals and vegetables partake of the general depravation which characterises malarious districts. The most efficient means of preventing the generation of the malarious poison, and, by consequence, the diseases to which it gives rise, are, the draining of swampy lands, and preventing the accumulation of putrid or putrescible vegetable or animal matter.

MICHAELMAS, the feast of St. Michael the archangel, 29th of September. Brady says it was first established in A.D. 487. Michaelmas-day is one of the regular periods, in this country, for settling rents; and an old custom is still in use of having a roast goose to dinner on that day, probably because geese are at this time most plentiful and in the highest perfection. There were formerly many superstitions connected with the observance of this day.

(Brand's *Popular Antiquities*, Sir H. Ellis's edit., 1841.)

MICROMETER (from *μικρός* small, and *μέτρον* a measure), the term generally applied to contrivances for measuring small spaces or angles with great accuracy or convenience.

The word is not applied to some artifices for subdividing the graduations of an astronomical instrument (for these see *VERNIER*), nor when a magnified portion of a subsidiary arc is used, which may be best considered under the heads of *SECTOR*, and *ZENITH SECTOR*, though they come properly under the definition. We shall follow the usual meaning of the term.

1. *Wire Micrometer*.—When the rays from any bright object fall upon a convex lens, an inverted image of the object is formed, which may be viewed by the eye-piece as if it were a material body. If a fine wire or spider's web be stretched across the telescope tube at the place where the image is formed, this too will be seen distinctly through the eye-piece. Instead of fixing the wire to the telescope tube, it is stretched across a sliding-piece, which is moved by a screw perpendicularly to the length of the telescope, and can thus be made to measure the image in terms of the revolutions and parts of the screw. The head of the screw is divided, and there is an index by which the parts are read off. A little tongue passing over the notches of a plate notes the whole number of revolutions.

An English gentleman named Gascoigne seems first to have applied this principle to practice, but he unfortunately lost his life, in 1644, in the great civil war; and though his telescope fell into Townley's hands, and was used by him, the construction does not seem to have been generally known until it was re-invented by Auzout in 1666. Different improvements were gradually made nearly up to the present time.

The plate carrying the wire is drawn by the screw, and held back by springs, which prevent any lost time. A micrometer of this kind is now generally applied to circles, transits, and theodolites, in addition to the fixed wires, which of course are always necessary. There are two verifications: first, the ascertaining the value of a revolution of the screw; and secondly, determining the reading of the screw-head when the moveable wire coincides with the fixed wire. In a circle or theodolite the micrometer wire is placed upon a sharp distant object, and the divided limb read off. The screw is turned through several revolutions, and the object is again bisected by moving the whole instrument by its tangent screw, and the divided limb read off a second time. We have then the same angle measured in revolutions of the screw and in the divisions of the instrument, and by a simple proportion have the value of a revolution and of a part. With a transit, the passage of Polaris over the micrometer wire is observed after successive revolutions of the screw. The angular motion of Polaris for the intervals is computed from the polar distance, and thus the value in arc obtained for a revolution of the screw. To determine the zero position of the micrometer wire, the moveable wire is brought to touch the fixed wire, first on one side and then on the other, and the screw-head read off each time. The mean of the two readings will be that when the two wires are exactly superimposed.

The *position wire micrometer* is much used for observations of double stars, and is the wire micrometer proper for equatorials. In this construction there are two wires parallel to each other, each moveable by its own screw: the whole apparatus can also be turned round in the plane of the wires, so as to place the wires in any direction, the angle round which it is turned being read off by two verniers upon a small circle called the *position circle*. In measuring a double star the wires are brought near each other, and the apparatus turned round until the two stars are either threaded on one of the wires, or, being placed between them, are judged to lie in the same direction. The division of the micrometer circle is then read off, and the observation in position is made. Now, by the divided circle of the micrometer turn the apparatus round 90° , and the wires will be at right angles to the line joining the two stars. By moving the equatorial, place one wire A on one of the stars, and place the other wire B, by its screw, on the second star. Read off the screw-head of B, and then place A on the second star by moving the equatorial, and B on the first by moving its screw, and read off the revolutions and parts of B. The difference of the two readings of B will give, in revolutions and parts of the screw, twice the angle between the two stars. The process may be repeated, keeping B fixed and moving A. Before or after a series of observations the zero or index error of the position circle should be ascertained. Place the instrument nearly in the meridian, and make a star run along one of the wires from end to end. Read and note the position circle, which should mark 90° and 270° , and the difference from this is the correction to be applied to all the angles of position observed during the evening. The value of a revolution of the screw may be determined by separating the two wires a given number of revolutions, and observing a series of transits of known stars over them. As large equatorials are always carried by a clock movement, we should recommend fixing the *position micrometer* upon a *slipping-piece*, by which a small motion up or down or to the right or left can be given to the wires without meddling with the clock or the equatorial. With this apparatus the measurement of double stars is perfectly easy. The wire micrometer requires illumination for seeing the wires, and the light thus admitted often obliterates faint and ill-defined objects.

The micrometer microscope, for reading off the divisions of graduated circles, depends upon the same principle as the wire micrometer. An enlarged image of the divisions of the limb of the circle is formed, and this image is measured by the revolutions and parts of a screw. [CIRCLE.]

2. The *divided object-glass micrometer* and *heliometer*. If an object-glass be cut across so as to form two semicircles, and the semilenses be separated by sliding one beyond the other, each portion will form its proper image, and these will retreat from each other as the semilenses are moved. The semilenses are mounted on slides, and the quantity of separation is read off upon a scale. In Bessel's heliometer, a very fine and perfect instrument of this class, the focal length of the object-glass is eight French feet, and the aperture nearly six French inches. A description and plate will be found in the 'Astronomische Nachrichten,' No. 189. The only objection which can be made to this species of micrometer, besides the extreme difficulty of constructing it, is, that stars are not seen so round and well defined as in an entire object-glass. Bessel's measures of double stars are, however, so far as we can judge, the most accurate that have yet been made. Suppose a double star is to be measured with the heliometer: the whole of the object end is turned round, until four stars appear in a right line, and the semilenses are separated until the stars appear to be exactly at the same distance from each other, when the scale is read off. The semilenses are then shifted in a contrary direction, sliding the two images over each other, until they again appear to be at equal distances, and the scale is again read off. The separation of the scale is four times the angular distance between the stars. There is a position circle, on which the direction of the stars is read off. In measuring the diameters of the sun, planets, &c., the two images are made to touch on opposite sides; and in observations of Halley's comet it was

made to coincide with the neighbouring stars. The divided object-glass micrometer is on the same principle as the heliometer; a cap containing the divided lenses is placed over the object-glass of the telescope. A similar micrometer may be obtained by dividing one of the lenses of an eye-piece; and it seems probable that, with large telescopes, this micrometer may be of considerable use in measuring small angles. There is a good deal of colour in the images, but not at the point of contact. Micrometers of this class require no illumination.

3. *Reticle and circular micrometer*. The micrometers hitherto described are applied to the accurate measures of small angles; the present class, though very useful in certain cases, are of much lower pretensions. The reticle, or diaphragm, as it is sometimes called, is any fixed arrangement of wires or bars which can be applied to a telescope for the purpose of measurement. They are chiefly used when an object will not admit of illumination, or where the astronomer has no accurately divided instrument at his disposal, or, as in the case of La Caille at the Cape of Good Hope, when the object is to fix approximately a greater number of stars than could be done in the same time with ordinary instruments. Suppose a cross like an X or V to be cut out of brass-plate and inserted in the principal focus of a telescope with the axis of the letter in a meridian. A star in passing through the field is occulted at its passage behind each of the bars, and the time noted. The *interval* will show, by an easy calculation, how far it passes from the vertex; and the *mean* of the times, the moment when it passes the axis of the diaphragm. If the true position of any one star so passing is known from any other source, all the other stars can be thus determined differentially with respect to it. The method is not very accurate, but may often be applied advantageously and with very small instrumental means. If a fine wire be drawn perpendicular to the axis, and a bright star, observed with illumination, be made to run along the wire, the axis of the diaphragm can be set in a meridian, and that is the only verification necessary. The computation in declination will be least if the angle between the bars is such that the base of the triangle is equal to its altitude. This reticle is very convenient for mapping, if placed in the meridian, or for cometary observation, if the telescope is mounted as an equatorial, however rudely.

The circular micrometer was introduced, we believe, by Olbers, and perfected by Fraunhofer ('Astron. Nachricht.' iv. 22). A metal ring is set in the centre of a perforated glass plate, and the outer and inner edge of the ring is turned true. The plate is fixed in the focus of a telescope, and the appearance is that of a ring suspended in the heavens. The telescope is pointed, and the observer notes the time when a star disappears at the outer ring, re-appears on the inner ring, disappears again, and finally re-appears. If two stars be thus observed, it is clear that when a mean is taken of the disappearances and re-appearances of each, that the difference between the two means will be the difference of right ascension between the two stars, and therefore that if one be known, the other is determined. Again, if the diameter of the ring has been determined, and the declination of the stars nearly known, the time of describing the chord of the ring will give, by an easy computation, the distance of the chord from the centre, and that the more accurately the smaller the chord described. The sum or difference of these two distances is the difference of the stars in declination. The computation of the second star with its approximate declination may be repeated if the stars are near the pole. It will be seen that nothing is required for the circular micrometer but the power of fixing the telescope for a few minutes until a known star passes the field, and that no illumination is required. It is especially the apparatus for determining the place of a faint comet or planet, and in the hands of Olbers, Harding, and many other German astronomers, has been of infinite use in cometary astronomy, and in the discovery and observation of the small planets. When the comet has a large motion, or when the position of the star is so low as to require attention to the difference of refraction, the computation is a little more complicated, but generally scarcely any computation is required, and the results, in right ascension at least, are good. The observations at the inner edge of the ring are to be preferred. When however the object will bear illumination, and the astronomer possesses a telescope so mounted that he can apply a wire micrometer to it, the results from this are incomparably more accurate, and the reticle above mentioned is certainly better for determining declination. Fraunhofer afterwards ('Astronom. Nach.' iv. 43) proposed another ring and reticle micrometer. He cut a series of rings or lines upon a piece of plane glass which he placed in the principal focus of the object-glass, and then by a side lamp illuminated the rings, leaving the rest of the field dark. It is evident that for certain observations this micrometer would have great advantages.

There are many other micrometers, but they are not in such general use as to demand any notice here. The reader will find them very fully and elaborately described in Pearson's 'Practical Astronomy,' vol. ii. See also Herschel and South's 'Observations of 380 Double and Triple Stars' (pp. 22, 23), containing tables of the values of Troughton's screws.

Since the above article was written by the Rev. R. Sheepshanks, micrometry, like all other branches of science, has put forth new shoots. In the original micrometer of Gascoigne, nicely ground parallel edges of brass plate were used, and Dr. Hooke made the important improve-

ment of substituting parallel hairs. Such an instrument embodies the principle of the best and most recent micrometers. The most difficult as well as important part of this instrument is the screw or screws by which the forks are moved. Their threads must not only be at the same distance from each other, but have their inclination equal all round. In the screw of Troughton's micrometer there are about 103 threads in an inch.

The usual method of finding the value of a revolution of the screw has been already given. The method of Professor Gauss of Göttingen is thus stated by Sir David Brewster ('Encyclopædia Britannica,' art. 'Micrometer') :—"He employs for this purpose a standard telescope, with a micrometer, the value of whose scale has been accurately determined. Since the wires of a telescope-micrometer adjusted to distinct vision of the stars or planets are accurately in the focus of parallel rays falling on the object-glass, it follows that rays issuing from the wires and falling on the inside of the object glass will emerge from it perfectly parallel. Now if we place the object-glass of the standard telescope close or near to that of the first telescope, the parallel rays formed by those issuing from its wires will be refracted to the focus of the standard telescope, and a distinct image of the wires will be there formed. The observer therefore when he looks into the standard telescope will see distinctly the wires of the first telescope, and by means of his micrometer he will be able to measure exactly the angular distance of these wires at whatever distance they may happen to be placed. This angular distance, divided by the revolutions and parts of a revolution which are necessary to bring the wires of the first telescope to the zero of their scale, will give the value of one revolution of the screw, or of one unit of the scale."

The parallel fibres of a micrometer must be extremely fine, and of uniform diameter. Since Hooke's time, wires and fibres of silk have been used instead of hairs. Troughton introduced the spider's line, which he found to be sufficiently fine, opaque, and elastic to answer the purpose: the stretcher, or long line which sustains the web, being alone adapted. The fibres of spun glass, of melted sealing-wax, of asbestos, and the minute crystals of mezzolite have also been used; but Wollaston's fine platinum wire [DUCTILITY] has of late years been preferred. These wires offer another advantage in the method of illuminating them, which in the transit instrument is generally done by means of a lamp, the light of which passes along the horizontal axis to a small speculum which reflects it upon the wire. The new method is to make the wires red hot by transmitting a voltaic current through them. Arago (who first adopted, if he did not first suggest the idea) feared that the images of objects beyond and apparently near the heated wire would undulate, but such was not found to be the case. This method of illumination has been used for the wires of the microscopic micrometers attached to the Oxford heliometer [HELIOMETER]. M. Porro's mode of illuminating the wires is to mount them on glass plates, the edges of which are formed into suitable curves, so as to introduce a thin vein of light perpendicularly to the axis of the telescope, so that the wires appear of a silvery white in a dark field. Brewster also proposed to obtain micrometer lines by placing in the field of view the reflected images of a fixed, or moveable system of wires, or of lucid discs, attached to the side of the eye-piece. The same distinguished optician has also proposed what he calls *photographic micrometers*. The reader is of course aware of the ease with which microscopic photographs can be impressed upon a film of collodion—as many as 10,000 portraits having been introduced into a square inch. "If a system of opaque or transparent lines be impressed upon the collodion photographically, when reduced to the minutest size, from a system of large and sharply defined lines, we shall have the most perfect micrometrical scale that can be conceived, the portion of the collodion that contains no nitrate of silver being as transparent as if the dark spaces were solid wires or metallic plates, placed in the focus of the eye-glass."

The plan of opening and shutting a pair of parallel wires optically instead of mechanically, and of using it as a general principle in micrometers, has also been applied; but for the details we must refer to the treatise above quoted, in which will also be found minute details respecting various forms of double-image micrometers, in which two singly refracting lenses, semi-lenses, or prisms, are separated by screws, or where the two images are separated optically, or in which the two images are formed by double refraction, and many others.

For a description of micrometers for microscopes see MICROSCOPE.

MICROCOSMIC SALT (NaO , NH_4O , HO , PO_5). The tribasic phosphate of soda, water, and ammonia; a salt much used as a flux in blowpipe experiments. [BLOWPIPE.]

MICROSCOPE, the name of an instrument for enabling the eye to see distinctly objects which are placed at a very short distance from it, or to see magnified images of small objects, and therefore to see smaller objects than would otherwise be visible. The name is derived from the two Greek words, expressing this property, *μικρός*, *small*, and *σκοπέω*, *to see*.

So little is known of the early history of the microscope, and so certain is it that the magnifying power of lenses must have been discovered as soon as lenses were made, that there is no reason for hazarding any doubtful speculations on the question of discovery. We shall proceed therefore at once to describe the simplest forms of microscopes, to explain their later and more important improvements, and finally to exhibit the instrument in its present perfect state.

In doing this we shall assume that the reader is familiar with the information contained in the articles LIGHT, LENS, ACHROMATIC, ABERRATION, and the other subdivisions of the science of Optics which are treated of in this work.

The use of the term *magnifying* has led many into a misconception of the nature of the effect produced by convex lenses. It is not always understood that the so-called magnifying power of a lens applied to the eye, as in a microscope, is derived from its enabling the eye to approach more nearly to its object than would otherwise be compatible with distinct vision. The common occurrence of walking across the street to read a bill is in fact magnifying the bill by approach; and the observer, at every step he takes, makes a change in the optical arrangement of his eye, to adapt it to the lessening distance between himself and the object of his inquiry. This power of spontaneous adjustment is so unconsciously exerted, that unless the attention be called to it by circumstances, we are totally unaware of its exercise.

In the case just mentioned the bill would be read with eyes in a very different state of adjustment from that in which it was discovered on the opposite side of the street, but no conviction of this fact would be impressed upon the mind. If however the supposed individual should perceive on some part of the paper a small speck, which he suspects to be a minute insect, and if he should attempt a very close approach of his eye for the purpose of verifying his suspicion, he would presently find that the power of natural adjustment has a limit; for when his eye has arrived within about ten inches, he will discover that a further approach produces only confusion. But if, as he continues to approach, he were to place before his eye a series of properly arranged convex lenses he would see the object gradually and distinctly increase in apparent size by the mere continuance of the operation of approaching. Yet the glasses applied to the eye during the approach from ten inches to one inch, would have done nothing more than had been previously done by the eye itself during the approach from fifty feet to one foot. In both cases the magnifying is effected really by the approach, the lenses merely rendering the latter periods of the approach compatible with distinct vision.

A very striking proof of this statement may be obtained by the following simple and instructive experiment. Take any minute object, a very small insect for instance, held on a pin or gummed to a slip of glass; then present it to a strong light, and look at it through the finest needle-hole in a blackened card placed about an inch before it. The insect will appear quite distinct, and about ten times larger than its usual size. Then suddenly withdraw the card without disturbing the object, which will instantly become indistinct and nearly invisible. The reason is, that the naked eye cannot see at so small a distance as one inch. But the card with the hole having enabled the eye to approach within an inch, and to see distinctly at that distance, is thus proved to be as decidedly a magnifying instrument as any lens or combination of lenses.

This description of magnifying power does not apply to such instruments as the solar or gas microscope, by which we look not at the object itself, but at its shadow or picture on the wall; and the description will require some modification in treating of the compound microscope, where, as in the telescope, an image or picture is formed by one lens, that image or picture being viewed as an original object by another lens.

It is nevertheless so important to obtain a clear notion of the real nature of the effect produced by a lens applied to the eye, that we will adduce the instance of spectacles to render the point more familiar. If the person who has been supposed to cross the street for the purpose of reading a bill had been aged, the limit to the power of adjustment would have been discovered at a greater distance, and without so severe a test as the supposed insect. The eyes of the very aged generally lose the power of adjustment at a distance of thirty or forty inches instead of ten, and the spectacles worn in consequence are as much magnifying glasses to them as the lenses employed by younger eyes to examine the most minute objects. Spectacles are magnifying glasses to the aged because they enable such persons to see as closely to their objects as the young, and therefore to see the objects larger than they could themselves otherwise see them, but not larger than they are seen by the unassisted younger eye.

In saying that an object appears larger at one time, or to one person, than another, it is necessary to guard against misconception. By the apparent size of an object we mean the angle it subtends at the eye, or the angle formed by two lines drawn from the centre of the eye to the extremities of the object. In *fig. 1*, the lines AE and BE

drawn from the eye to the object form the angle AEB , which, when the angle is small, is nearly twice as great as the angle CED formed by

lines drawn from a similar arrow at twice the distance. The arrow *AB* will therefore appear nearly twice as long as *CD*, being seen under twice the angle, and in the same proportion for any greater or lesser difference in distance. The angle in question is called the angle of vision, or the visual angle.

The angle of vision must however not be confounded with the angle of the pencil of light by which an object is seen, and which is explained in *fig. 2*. Here we have drawn two arrows placed in relation to the

eye as before, and from the centre of each have drawn lines exhibiting the quantity of light which each point will send into the eye at the respective distances.

Now if *EF* represent the diameter of the pupil, the angle *EAF* shows the size of the cone or pencil of light which enters the eye from the point *A*, and in like manner the angle *EBF* is that of the pencil emanating from *B*, and entering the eye. Then, since *EAF* is double *EBF*, it is evident that *A* is seen by four times the quantity of light which could be received from an equally illuminated point at *B*; so that the nearer body would appear brighter if it did not appear larger; but as its apparent area is increased four times, as well as its light, no difference in this respect is discovered. But if we could find means to send into the eye a larger pencil of light, as for instance that shown by the lines *GAH*, without increasing the apparent size in the same proportion, it is evident that we should obtain a benefit totally distinct from that of increased magnitude, and one which is in some cases of even more importance than size in developing the structure of what we wish to examine. This, it will be hereafter shown, is sometimes done; for the present, we wish merely to explain clearly the distinction between apparent magnitude, or the angle under which the object is seen, and apparent brightness, or the angle of the pencil of light by which each of its points is seen, and with these explanations we shall continue to employ the common expressions magnifying glass and magnifying power.

The magnifying power of a single lens depends upon its focal length, the object being in fact placed nearly in its principal focus, or so that the light which diverges from each point may, after refraction by the lens, proceed in parallel lines to the eye, or as nearly so as is requisite for distinct vision. In *fig. 3*, *AB* is a double convex lens, near which

is a small arrow to represent the object under examination, and the cones drawn from its extremities are portions of the rays of light diverging from those points and falling upon the lens. These rays, if suffered to fall at once upon the pupil, would be too divergent to permit their being brought to a focus upon the retina by the optical arrangements of the eye. But being first passed through the lens, they are bent into nearly parallel lines, or into lines diverging from some points within the limits of distinct vision, as from *c* and *d*. Thus altered, the eye receives them precisely as if they emanated from a larger arrow placed at *CD*, which we may suppose to be ten inches from the eye, and then the difference between the real and the imaginary arrow is called the magnifying power of the lens in question.

From what has been said it will be evident that two persons whose eyes differed as to the distance at which they obtained distinct vision, would give different results as to the magnifying power of a lens. To one who can see distinctly with the naked eye at a distance of five inches, the magnifying power would seem (and would indeed be) only half what we have assumed. Such instances are however rare; the focal length of the eye usually ranges from six to twelve or fourteen inches, so that the distance we first assumed of ten inches is very near the true average, and is a convenient number, inasmuch as a cipher added to the denominator of the fraction which expresses the focal length of a lens gives its magnifying power. Thus a lens whose focal length is one-sixteenth of an inch is said to magnify 160 times.

ARTS AND SCI. DIV. VOL. V.

When the focal length of a lens is very small it is difficult to measure accurately the distance between its centre and its object. In such cases the best way to obtain the focal length for parallel or nearly parallel rays is to view the image of some distant object formed by the lens in question through another lens of one inch solar focal length, keeping both eyes open and comparing the image presented through the two lenses with that of the naked eye. The proportion between the two images so seen will be the focal length required. Thus if the image seen by the naked eye is ten times as large as that shown by the lenses, the focal length of the lens in question is one-tenth of an inch. The panes of glass in a window, or courses of bricks in a wall, are convenient objects for this purpose.

In whichever way the focal length of the lens is ascertained, the rules given for deducing its magnifying power are not rigorously correct, though they are sufficiently so for all practical purposes, particularly as the whole rests on an assumption in regard to the focal length of the eye, and as it does not in any way affect the actual measurement of the object. To calculate with great precision the magnifying power of a lens with a given focal length of eye, it is necessary that the thickness of the lens be taken into the account, and also the focal length of the eye itself.

We have hitherto considered a magnifying lens only in reference to its enlargement of the object, or the increase of the angle under which the object is seen. A further and equally important consideration is that of the number of rays or quantity of light by which every point of the object is rendered visible. The naked eye as shown in *fig. 2*, admits from each point of every visible object a cone of light having the diameter of the pupil for its base, and most persons are familiar with that beautiful provision by which in cases of excessive brilliancy the pupil spontaneously contracts to reduce the cone of admitted light within bearable limits. This effect is still further produced in the experiment already described, of looking at an object through a needle-hole in a card, which is equivalent to reducing the pupil to the size of a needle-hole. Seen in this way the object becomes comparatively dark or obscure, because each point is seen by means of a very small cone of light, and a little consideration will suffice to explain the different effects produced by the needle-hole and the lens. Both change the angular value of the cone of light presented to the eye, but the lens changes the angle by bending the extreme rays within the limits suited to distinct vision, while the needle-hole effects the same purpose by cutting off the rays which exceed those limits.

It has been shown that removing a brilliant object to a greater distance will reduce the quantity of light which each point sends into the eye, as effectually as viewing it through a needle-hole; and magnifying an object by a lens has been shown to be the same thing in some respects as removing it to a greater distance. We have to see the magnified picture by the light emanating from the small object, and it becomes a matter of difficulty to obtain from each point a sufficient quantity of light to bear the diffusion of a great magnifying power. We want to perform an operation just the reverse of applying the card with the needle-hole to the eye—we want in some cases to bring into the eye the largest possible pencil of light from each point of the object.

Referring to *fig. 3*, it will be observed that if the eye could see the small arrow at the distance there shown without the intervention of the lens, only a very small portion of the cones of light drawn from its extremities would enter the pupil; whereas we have supposed that after being bent by the lens the whole of this light enters the eye as part of the cones of smaller angle whose summits are at *c* and *d*. These cones will further explain the difference between large and small pencils of light; those from the small arrow are large pencils; the dotted cones from the large arrow are small pencils.

In assuming that the whole of this light could have been suffered to enter the eye through the lens *AB*, we did so for the sake of not perplexing the reader with too many considerations at once. He must now learn that so large a pencil of light passing through a single lens would be so distorted by the spherical figure of the lens, and by the chromatic dispersion of the glass, as to produce a very confused and imperfect image. This confusion may be greatly diminished by reducing the pencil; for instance, by applying a stop, as it is called, to the lens, which is neither more nor less than the needle-hole applied to the eye. A small pencil of light may be thus transmitted through a single lens without suffering from spherical aberration or chromatic dispersion any amount of distortion which will materially affect the figure of the object; but this quantity of light is insufficient to bear diffusion over the magnified picture, which is therefore too obscure to exhibit what we most desire to see—those beautiful and delicate markings by which one kind of organic matter is distinguished from another. With a small aperture these markings are not seen at all; with a large aperture and a single lens they exhibit a faint nebulous appearance enveloped in a chromatic mist, a state which is of course utterly valueless to the naturalist, and not even amusing to the amateur.

It becomes therefore a most important problem to reconcile a large aperture with distinctness, or, as it is called, *definition*; and this has been done in a considerable degree by effecting the required amount of refraction through two or more lenses instead of one, thus reducing the angles of incidence and refraction, and producing other effects

which will be shortly noticed. This was first accomplished in a satisfactory manner by—

Dr. Wollaston's doublet,

invented by the celebrated philosopher whose name it bears; it consists of two plano-convex lenses (*fig. 4*) having their focal lengths in the proportion of 1 to 3, or nearly so, and placed at a distance which can be ascertained best by actual experiment. Their plane sides are placed towards the object, and the lens of shortest focal length next the object.

It appears that Dr. Wollaston was led to this invention by considering that the achromatic Huyghenian eye-piece, which will be hereafter described, would, if reversed, possess similar good properties as a simple microscope. But it will be evident when the eye-piece is understood, that the circumstances which render it achromatic are very imperfectly applicable to the simple microscope, and that the doublet, without a nice adjustment of the stop, would be valueless. Dr. Wollaston makes no allusion to a stop, nor is it certain that he contemplated its introduction, although his illness, which terminated fatally soon after the presentation of his paper, may account for the omission.

The nature of the corrections which take place in the doublet is explained in the annexed diagram (*fig. 5*), where $L O L'$ is the object, P a portion of the pupil, and $D D$ the stop, or limiting aperture.

Fig. 5.

Now, it will be observed that each of the pencils of light from the extremities $L L'$ of the object is rendered excentric by the stop, and of consequence each passes through the two lenses on opposite sides of their common axis $O P$; thus each becomes affected by opposite errors, which to some extent balance and correct each other. To take the pencil L , for instance, which enters the eye at $R B R B$, it is bent to the right at the first lens, and to the left at the second; and as each bending alters the direction of the blue rays more than the red, and moreover as the blue rays fall nearer the margin of the second lens, where the refraction, being more powerful than near the centre, compensates in some degree for the greater focal length of the second lens, the blue and red rays will emerge very nearly parallel, and of consequence colourless to the eye. At the same time the spherical aberration has been diminished by the circumstance that the side of the pencil which passes one lens nearest the axis passes the other nearest the margin.

This explanation applies only to the pencils near the extremities of the object. The central pencil, it is obvious, would pass both lenses symmetrically; the same portions of light occupying nearly the same relative places on both lenses. The blue light would enter the second lens nearer to its axis than the red, and being thus less refracted than the red by the second lens, a small amount of compensation would take place, quite different in principle and inferior in degree to that which is produced in the excentric pencils. In the intermediate spaces the corrections are still more imperfect and uncertain; and this explains the cause of the aberrations which must of necessity exist even in the best-made doublet. It is, however, infinitely superior to a single lens, and will transmit a pencil of an angle of from 35° to 50° without any very sensible errors. It exhibits therefore many of the usual test-objects in a very beautiful manner.

The next step in the improvement of the simple microscope bears more analogy to the eye-piece. This improvement was made by Mr.

Holland, and it consists (as shown in *fig. 6*) in substituting two lenses for the first in the doublet, and retaining the stop between them and the third. The first bending, being thus effected by two lenses instead of one, is accompanied by smaller aberrations, which are therefore more completely balanced or corrected at the second bending, in the opposite direction, by the third lens. This combination, though called a triplet, is essentially a doublet, in which the anterior lens is divided into two. For it must be recollected that the first pair of lenses merely accomplishes what might have been done, though with less precision, by one; but the two lenses of the doublet are opposed to each other; the second diminishing the magnifying power of the first. The first pair of lenses in the triplet concur in producing a certain amount of magnifying power, which is diminished in quantity and corrected as to aberration at the third lens by the change in relation to the position of the axis which takes place in the pencil between what is virtually the first and second lens. In this combination the errors are still further reduced by the close approximation to the object which causes the refractions to take place near the axis. Thus the transmission of a still larger angular pencil, namely 65° , is rendered compatible with distinctness, and a more intense image is presented to the eye.

Every increase in the number of lenses is attended with one drawback, from the circumstance that a certain portion of light is lost by reflection and absorption each time that the ray enters a new medium. This loss bears no sensible proportion to the gain arising from the increased aperture, which, being as the square of the diameter, multiplies rapidly; or if we estimate by the angle of the admitted pencil, which is more easily ascertained, the intensity will be as the square of twice the tangent of half the angle.

To explain this, let $D B$ (*fig. 7*) represent the diameter of the lens, or of that part of it which is really employed; $C A$ the perpendicular drawn from its centre, and $A B, A D$, the extreme rays of the incident pencil of light $D A B$. Then the diameter being $2 C B$, the area to which the intensity of vision is proportional will be $(2 C B)^2$, and $C B$ is evidently the tangent of the angle $C A B$, which is half the angle of the admitted pencil $D A B$. Or, if α be used to denote the angular aperture, the expression for the intensity is $(2 \tan. \frac{1}{2} \alpha)^2$, which increases so rapidly with the increase of α , as to make the loss of light by reflection and absorption of little consequence.

Fig. 7.

The combination of three lenses approaches, as has been stated, very close to the object; so close indeed as to prevent the use of more than three; and this constitutes a limit to the improvement of the simple microscope, (for it is called a simple microscope, although consisting of three lenses, and although a compound microscope may be made of only three or even two lenses;) but the different arrangement which gives rise to the term compound will be better understood when that instrument is explained.

Before we proceed to describe the simple microscope and its appendages, it will be well to explain such other points in reference to the form and materials of lenses as are most likely to be interesting.

A very useful form of lens was proposed by Dr. Wollaston, and called by him the periscopic lens. It consisted of two hemispherical lenses, cemented together by their plane faces, having a stop between them to limit the aperture. A similar proposal was made by Mr. Coddington, who, however, executed the project in a better manner, by cutting a groove in a whole sphere, and filling the groove with opaque matter. His lens, which is the well-known Coddington lens, is shown in *fig. 8*. It gives a large field of view, which is equally good in all directions, as it is evident that the pencils $A A'$ and $B B'$ pass through under precisely the same circumstances. Its spherical form has the further advantage of rendering the position in which it is held of comparatively little consequence. It is therefore very convenient as a hand-lens, but its definition is of course not so good as that of a well-made doublet or achromatic lens.

Fig. 8.

Another very useful form of doublet was proposed by Sir John Herschel, chiefly like the Coddington lens, for the sake of a wide field, and chiefly to be used in the hand. It is shown in *fig. 9*; it consists of a double convex or crossed lens, having the radii of curvature as 1 to 6, and of a plane concave lens whose focal length is to that of the convex lens as 13 to 5.

Various, indeed innumerable, other forms and combinations of lenses have been projected, some displaying much ingenuity, but few of any practical use. In the Catadioptric lenses the light emerges at right angles from its entering direction, being reflected from a surface cut at an angle of 45° to the axes of the curved surfaces.

It was at one time hoped, as the precious stones are more refractive than glass, and as the increased refractive power is unaccompanied by

Fig. 9.

a correspondent increase in chromatic dispersion, that they would furnish valuable materials for lenses, inasmuch as the refractions would be accomplished by shallower curves, and consequently with diminished spherical aberration. But these hopes were disappointed: everything that ingenuity and perseverance could accomplish was tried by Mr. Varley and Mr. Pritchard, under the patronage of Dr. Goring. It appeared, however, that the great reflective power, the doubly-refracting property, the colour, and the heterogeneous structure of the jewels which were tried, much more than counterbalanced the benefits arising from their greater refractive power, and left no doubt of the superiority of skilfully made glass doublets and triplets. The idea is now, in fact, abandoned; and the same remark is applicable to the attempts at constructing fluid lenses, and to the projects for giving to glass other than spherical surfaces.

By the term *simple microscope* is meant one in which the object is viewed directly through a lens or combination of lenses, just as we have supposed an arrow or an insect to be viewed through a glass held in the hand. When, however, the magnifying power of the glass is considerable, in other words, when its focal length is very short, and its proper distance from its object of consequence equally short, it requires to be placed at that proper distance with great precision: it cannot therefore be held with sufficient accuracy and steadiness by the unassisted hand, but must be mounted in a frame having a rack or screw to move it towards or from another frame or stage which holds the object. It is then called a microscope, and it is furnished, according to circumstances, with lenses and mirrors to collect and reflect the light upon the object, and with other conveniences which will now be described.

One of the best forms of a stand for a simple microscope is shown in *fig. 10*, where *A* is a brass pillar screwed to a tripod base; *B* is a broad stage for the objects, secured to the stem by screws, whose milled

Fig. 10.

heads are at *c*. By means of the large milled head *D*, a triangular bar, having a rack, is elevated out of the stem *A*, carrying the lens-holder *E*, which has a horizontal movement in one direction, by means of a rack worked by the milled head *F*, and in the other direction by turning on a circular pin. A concave mirror *G* reflects the light upwards through the hole in the stage, and a lens may be attached to the stage for the purpose of throwing light on an opaque object, in the same way that the forceps *H* for holding such objects is attached. This microscope is peculiarly adapted, by its broad stage and its general steadiness, for dissecting; and it is rendered more convenient for this purpose by placing it between two inclined planes of mahogany, which support the arms and elevate the wrists to the level of the stage. This apparatus is called the dissecting rest. When dissecting is not a

primary object, a joint may be made at the lower end of the stem *A*, to allow the whole to take an inclined position; and then the spring clips shown upon the stage are useful to retain the object in its place. Numerous convenient appendages may be made to accompany such microscopes, which it will be impossible to mention in detail: the most useful are Mr. Varley's capillary cages for containing animalculæ in water, and parts of aquatic plants; also his tubes for obtaining and separating such objects, and his phial and phial-holder for preserving and exhibiting small living specimens of the *Chara*, *Nitella*, and other similar plants, and observing their circulation. The phial-microscope affords facilities for observing the operations of minute vegetable and animal life.

The mode of illuminating objects is one on which we must give some further information, for the manner in which an object is lighted is second in importance only to the excellence of the glass through which it is seen. In investigating any new or unknown specimen, it should be viewed in turns by every description of light, direct and oblique, as a transparent object and as an opaque object, with strong and with faint light, with large angular pencils and with small angular pencils thrown in all possible directions. Every change will probably develop some new fact in reference to the structure of the object, which should itself be varied in the mode of mounting in every possible way. It should be seen both wet and dry, and immersed in fluids of various qualities and densities, such, for instance, as water, alcohol, oil, and Canada balsam, which last has a refractive power nearly equal to that of glass. If the object be delicate vegetable tissue, it will be in some respects rendered more visible by gentle heating or scorching by a clear fire placed between two plates of glass. In this way the spiral vessels of asparagus and other similar vegetables may be beautifully displayed. Dyeing the objects in tincture of iodine will in some cases answer this purpose better.

But the principal question in regard to illumination is the mag-

Fig. 11.

nitude of the illuminating pencil, particularly in reference to transparent objects. Generally speaking the illuminating pencil should be as large as can be received by the lens, and no larger. Any light beyond this produces indistinctness and glare. The superfluous light from the mirror may be cut off by a screen having various-sized apertures placed below the stage; but the best mode of illumination is that proposed by Dr. Wollaston, and called the Wollaston condenser. A tube is placed below the stage of the instrument containing a lens *A B* (*fig. 11*), which can be elevated or depressed within certain limits at pleasure; and at the lower end is a stop with a limited aperture *C D*. A plane mirror *E F* receives the rays of light *L L* from the sky or a white cloud, which last is the best source of light, and reflects them upwards through the aperture in *C D*, so that they are refracted, and form an image of the aperture at *G*, which is supposed to be nearly the place of the object. The object is sometimes best seen when the image of the aperture is also best seen; and sometimes it is best to elevate the summit *G* of the cone *A B G* above the object, and at others to depress it below: all which is done at pleasure by the power of moving the lens *A B*. If artificial light (as a lamp or candle) be employed, the flame must be placed in the principal focus of a large detached lens on a stand, so that the rays *L L* may fall in parallel lines on the mirror, or as they would fall from the cloud. This will be found an advantage, not only when the Wollaston condenser is employed, but also when the mirror and diaphragm are used. A good mode of imitating artificially the light of a white cloud opposite the sun has been proposed by Mr. Varley: he covers the surface of the mirror under the stage with carbonate of soda or any similar material,

and then concentrates the sun's light upon its surface by a large condensing lens. The intense white light diffused from the surface of the soda forms an excellent substitute for the white cloud, which, when opposite the sun and of considerable size, is the best day-light, as the pure sky opposite to the sun is the worst.

The Compound Microscope may, as before stated, consist of only two lenses, while a simple microscope has been shown to contain sometimes three. In the triplet for the simple microscope, however, it was explained that the effect of the two first lenses was to do what might have been accomplished, though not so well, by one; and the third merely effected certain modifications in the light before it entered the eye. But in the compound microscope the two lenses have totally different functions; the first receives the rays from the object, and, bringing them to new foci, forms an image, which the second lens treats as an original object, and magnifies it just as the single microscope magnified the object itself.

The annexed figure (12) shows the course of the rays through a compound microscope of two lenses. The rays proceeding from the object $A B$ are so acted upon by the lens $C D$, near it, and thence called the objective, that they are converged to foci in $A'B'$, where they form an enlarged image of the object, as would be evident if a piece of oiled paper or ground glass were placed there to receive them. They are not so intercepted, and therefore the image is not rendered visible at that place; but their further progress is similar to what it would have been had they really proceeded from an object at $A'B'$. They are at length received by the eye-lens $L M$, which acts upon them as the simple microscope has been described to act on the light proceeding from its objects. They are bent so that they may enter the eye at E in parallel lines, or as nearly so as is requisite for distinct vision. When we say that the rays enter the eye in nearly parallel lines, we mean only those which proceed from one point of the original object. Thus the two parallel rays $M E$ have proceeded from and are part of the cone of rays $C A D$, emanating from the point A of the arrow; but they do not form two pictures in the eye, because any number of parallel rays which the pupil can receive will be converged to a point by the eye, and will convey the impression of one point to the mind. In like manner the rays $L E$ are part of the cone of rays emanating from B , and the angle $L E M$ is that under which the eye will see the magnified image of the arrow, which is evidently many times greater than the arrow could be made to occupy in the naked eye at any distance within the limits of distinct vision. The magnifying power depends on two circumstances: first, on the ratio between the anterior distance $A C$ or $B D$ and the posterior focal length $C B$ or $D A'$; and secondly, on the power of the eye-lens $L M$. The first ratio is the same as that between the object $A B$ and the image $A'B'$; this and the focal length or power of the eye-lens are both easily obtained, and their product is the power of the compound instrument.

Since the power depends on the ratio between the anterior and posterior foci of the objective, it is evident that by increasing that ratio any power may be obtained, the same eye-glass being used; or, having determined the first, any further power may be obtained by increasing that of the eye-glass; and thus, by a pre-arrangement of the relative proportions in which the magnifying power shall be divided between the objective and the eye-glass, almost any given distance (within certain limits) between the first and its object may be secured. This is one valuable peculiarity of the compound instrument; and another is the large field, or large angle of view, which may be obtained, every part of which will be nearly equally good; whereas with the best simple microscopes the field is small, and is good only in the centre. The field of the compound instrument is further increased by using two glasses at the eye-end; the first being called, from its purpose, the field-glass, and the two constituting what is called the eye-piece. This will be more particularly explained in the figure of the achromatic compound microscope presently given.

For upwards of a century the compound microscope, notwithstanding the advantages above mentioned, was a comparatively feeble and inefficient instrument, owing to the distance which the light had to traverse, and the consequent increase of the chromatic and spherical aberrations. To explain this we have drawn in *fig. 12* a second image

near $A'B'$, the fact being that the object-glass would not form one image, as has been supposed, but an infinite number of variously-coloured and various-sized images, occupying the space between the two dotted arrows. Those nearest the object-glass would be red, and those nearest the eye-glass would be blue. The effect of this is to produce so much confusion, that the instrument was reduced to a mere toy, although these errors were diminished to the utmost possible extent by limiting the aperture of the object-glass, and thus restricting the angle of the pencil of light from each point of the object. But this involved the defects, already explained, of making the picture obscure, so that on the whole the best compound instruments were inferior to the simple microscopes of a single lens, with which indeed all the important observations of the last century were made.

Even after the improvement of the simple microscope by the use of doublets and triplets, the long course of the rays and the large angular pencil required in the compound instrument deterred the most sanguine from anticipating the period when they should be conducted through such a path free both from spherical and chromatic errors. Philosophers of no less eminence than M. Biot and Dr. Wollaston had predicted that the compound would never rival the simple microscope, and that the idea of achromatising its object-glass was hopeless. Nor can these opinions be wondered at when we consider how many years the achromatic telescope had existed without an attempt to apply its principles to the compound microscope. When we consider the smallness of the pencil required by the telescope, and the enormous increase of difficulty attending every enlargement of the pencil—when we consider further that these difficulties had to be contended with and removed by operations on portions of glass so small that they are themselves almost microscopic objects, we shall not be surprised that even a cautious philosopher and most able manipulator like Dr. Wollaston should prescribe limits to improvement.

Fortunately for science, and especially for the departments of animal and vegetable physiology, these predictions have been shown to be unfounded. The compound microscope has been elevated from the condition we have described to that of being the most important instrument ever bestowed by art upon the investigator of nature. It now holds a very high rank among philosophical implements, while the transcendent beauties of form, colour, and organisation which it reveals to us in the minute works of nature, render it subservient to the most delightful and instructive pursuits. To these claims on our attention it appears likely to add a third of still higher importance. The microscopic examination of the blood and other human organic matter will in all probability afford more satisfactory and conclusive evidence regarding the nature and seat of disease than any hitherto appealed to, and will of consequence lead to similar certainty in the choice and application of remedies.

Soon after the year 1820 a series of experiments was begun in France by M. Selligues, which were followed up by Fraunhofer at Munich, by Amici at Modena, by M. Chevalier at Paris, and by the late Mr. Tulley in London. In 1824 the last-named excellent artist, without knowing what had been done on the Continent, made the attempt to construct an achromatic objective for a compound microscope, and produced one of nine-tenths of an inch focal length, composed of three lenses, and transmitting a pencil of eighteen degrees. This was the first that had been made in England; and it is due to Mr. Tulley to say, that as regards accurate correction throughout the field, that glass has not been excelled by any subsequent combination of three lenses. Such an angular pencil, and such a focal length, would bear an eye-piece adapted to produce a gross magnifying power of one hundred and twenty. Mr. Tulley afterwards made a combination to be placed in front of the first-mentioned, which increased the angle of the transmitted pencil to thirty-eight degrees, and bore a power of three hundred.

While these practical investigations were in progress, the subject of achromatism engaged the attention of some of the most profound mathematicians in England. Sir John Herschel, Professor Airy, Professor Barlow, Mr. Coddington, and others, contributed largely to the theoretical examination of the subject; and though the results of their labours were not immediately applicable to the microscope, they essentially promoted its improvement.

For some time prior to 1829 the subject had occupied the mind of a gentleman, who, not entirely practical, like the first, nor purely mathematical, like the last-mentioned class of inquirers, was led to the discovery of certain properties in achromatic combinations which had been before unobserved. These were afterwards experimentally verified; and in the year 1829 a paper on the subject, by the discoverer, Mr. Joseph Jackson Lister, was read and published by the Royal Society. The principles and results thus obtained enabled Mr. Lister to form a combination of lenses which transmitted a pencil of fifty degrees, with a large field correct in every part: as this paper was the foundation of the recent improvements in achromatic microscopes, and as its results are indispensable to all who would make or understand the instrument, we shall give the more important parts of it in detail, and in Mr. Lister's own words.

"I would premise that the plano-concave form for the correcting flint lens has in that quality a strong recommendation, particularly as it obviates the danger of error which otherwise exists in centring the two curves, and thereby admits of correct workmanship for a shorter

focus. To cement together also the two surfaces of the glass diminishes by very nearly half the loss of light from reflexion, which is considerable at the numerous surfaces of a combination. I have thought the clearness of the field and brightness of the picture evidently increased by doing this; it prevents any dewiness or vegetation from forming on the inner surfaces; and I see no disadvantage to be anticipated from it if they are of identical curves, and pressed closely together, and the cementing medium permanently homogeneous.

"These two conditions then, that the flint lens shall be plano-concave, and that it shall be joined by some cement to the convex, seem desirable to be taken as a basis for the microscopic object-glass, provided they can be reconciled with the destruction of the spherical and chromatic aberrations of a large pencil.

"Now in every such glass that has been tried by me which has had its correcting lens of either Swiss or English glass, with a double convex of plate, and has been made achromatic by the form given to the outer curve of the convex, the proportion has been such between the refractive and dispersive powers of its lenses, that its figure has been correct for rays issuing from some point in its axis not far from its principal focus on its plane side, and either tending to a conjugate focus within the tube of a microscope, or emerging nearly parallel.

"Let *AB* (fig. 13) be supposed such an object-glass, and let it be roughly considered as a plano-convex lens, with a curve *ABC* running through it, at which the spherical and chromatic errors are corrected which are generated at the two outer surfaces; and let the glass be thus free from aberration for rays *FDEG* issuing from the radiant point *F*, *HE* being a perpendicular to the convex surface, and *ID* to the plane one. Under these circumstances, the angle of emergence *GEH* much exceeds that of incidence *FDI*, being probably nearly three times as great.

"If the radiant is now made to approach the glass, so that the course of the ray *FDEG* shall be more divergent from the axis, as the angles of incidence and emergence become more nearly equal to each other, the spherical aberration produced by the two will be found to bear a less proportion to the opposing error of the single correcting curve *ABC*; for such a focus therefore the rays will be over-corrected.

"But if *F* still approaches the glass, the angle of incidence continues to increase with the increasing divergence of the ray, till it will exceed that of emergence, which has in the meanwhile been diminishing, and at length the spherical error produced by them will recover its original proportion to the opposite error of the curve of correction. When *F* has reached this point *F'* (at which the angle of incidence does not exceed that of emergence so much as it had at first come short of it), the rays again pass the glass free from spherical aberration.

"If *F* be carried from hence towards the glass, or outwards from its original place, the angle of incidence in the former case, or of emergence in the latter, becomes disproportionately effective, and either way the aberration exceeds the correction.

"These facts have been established by careful experiment: they accord with every appearance in such combinations of the plano-convex glasses as have come under my notice, and may, I believe, be extended to this rule, that in general an achromatic object-glass, of which the inner surfaces are in contact, or nearly so, will have on one side of it two foci in its axis, for the rays proceeding from which it will be truly corrected at a moderate aperture; that for the space between these two points its spherical aberration will be over-corrected, and beyond them either way under-corrected.

"The longer aplanatic focus may be found, when one of the plano-convex object-glasses is placed in a microscope, by shortening the tube, if the glass shows over-correction; if under-correction, by lengthening it, or by bringing the rays together, should they be parallel or divergent, by a very small good telescope. The shorter focus is got at by sliding the glass before another of sufficient length and large aperture that is finely corrected, and bringing it forwards till it gives the reflexion of a bright point from a globule of quicksilver, sharp and free from mist, when the distance can be taken between the glass and the object.

"The longer focus is the place at which to ascertain the utmost aperture that may be given to the glass, and where, in the absence of spherical error, its exact state of correction as to colour is seen most distinctly.

"The correction of the chromatic aberration, like that of the spherical, tends to excess in the marginal rays; so that if a glass which is achromatic, with a moderate aperture, has its cell opened wider, the circle of rays thus added to the pencil will be rather over-corrected as to colour.

"The same tendency to over-correction is produced, if, without varying the aperture, the divergence of the incident rays is much augmented, as in an object-glass placed in front of another; but gene-

rally in this position a part only of its aperture comes into use; so that the two properties mentioned neutralise each other, and its chromatic state remains unaltered. If for example the outstanding colours were observed at the longer focus to be green and claret, which show that the nearest practicable approach is made to the union of the spectrum, they usually continue nearly the same for the whole space between the foci, and for some distance beyond them either way.

"The places of these two foci and their proportions to each other depend on a variety of circumstances. In several object-glasses that I have had made for trial, plano-convex, with their inner surfaces cemented, their diameters the radius of the flint lens, and their colour pretty well corrected, those composed of dense flint and light plate have had the rays from the longer focus emerging nearly parallel; and this focus has been not quite three times the distance of the shorter from the glass: with English flint the rays have had more convergence, and the shorter focus has borne a rather less proportion to the longer.

"If the surfaces are not cemented, a striking effect is produced by minute differences in their curves. It may give some idea of this, that in a glass of which nearly the whole disc was covered with colour from contact of the lenses, the addition of a film of varnish, so thin that this colour was not destroyed by it, caused a sensible change in the spherical correction.

"I have found that whatever extended the longer aplanatic focus, and increased the convergence of its rays, diminished the relative length of the shorter. Thus by turning to the concave lens the flatter instead of the deeper side of a convex lens, whose radii were to each other as 31 to 35, the pencil of the longer aplanatic focus, from being greatly divergent, was brought to converge at a very small distance behind the glass; and the length of the shorter focus, which had been one-half that of the longer, became but one-sixth of it.

"The direction of the aplanatic pencils appears to be scarcely affected by the differences in the thickness of glasses, if their state as to colour is the same.

"One other property of the double object-glass remains to be mentioned, which is, that when the longer aplanatic focus is used, the marginal rays of a pencil not coincident with the axis of the glass are distorted, so that a coma is thrown outwards; while the contrary effect of a coma directed towards the centre of the field is produced by the rays from the shorter focus. These peculiarities of the coma seem inseparable attendants on the two foci, and are as conspicuous in the achromatic meniscus as in the plano-convex object-glass.

"Of several purposes to which the particulars just given seem applicable, I must at present confine myself to the most obvious one. They furnish the means of destroying with the utmost ease both aberrations in a large focal pencil, and of thus surmounting what has hitherto been the chief obstacle to the perfection of the microscope. And when it is considered that the curves of its diminutive object-glasses have required to be at least as exactly proportioned as those of a large telescope to give the image of a bright point equally sharp and colourless, and that any change made to correct one aberration was liable to disturb the other, some idea may be formed of what the amount of that obstacle must have been. It will however be evident that if any object-glass is but made achromatic, with its lenses truly worked and cemented, so that their axes coincide, it may with certainty be connected with another possessing the same requisites and of suitable focus, so that the combination shall be free from spherical error also in the centre of its field. For this the rays have only to be received by the front glass *B* (fig. 14) from its shorter aplanatic focus *F'*, and transmitted in the direction of the longer correct pencil *FA* of the other glass *A*. It is desirable that the latter pencil should neither converge to a very short focus nor be more than very slightly if at all divergent; and a little attention at first to the kind of glass used will keep it within this range, the denser flint being suited to the glasses of shorter focus and larger angle of aperture.

"The adjustment of the microscope is then perfected, if necessary, by slightly varying the distance between the object-glasses; and after that is done, the length of the tube which carries the eye-pieces may be altered greatly without disturbing the correction, opposite errors which balance each other being produced by the change.

"If the two glasses which in the diagram are drawn at some distance apart are brought nearer together (if the place of *A* for instance is carried to the dotted figure), the rays transmitted by *B* in the direction of the longer aplanatic pencil of *A* will plainly be derived from some point *Z* more distant than *F'*, and lying between the aplanatic foci of *B*; therefore (according to what has been stated) this glass, and consequently the combination, will then be spherically over-corrected. If on the other hand the distance between *A* and *B* is increased, the opposite effects are of course produced.

"In combining several glasses together it is often convenient to

transmit an under-corrected pencil from the front glass, and to counter-act its error by over-correction in the middle one.

"Slight errors in colour may in the same manner be destroyed by opposite ones; and on the principles described we not only acquire fine correction for the central ray, but, by the opposite effects at the two foci on the transverse pencil, all coma can be destroyed, and the whole field rendered beautifully flat and distinct."

Mr. Lister's paper enters into further particulars, which are not essential to the comprehension of the subject. It is sufficient to say that his investigations and results proved to be of the highest value to the practical optician, and the progress of improvement was in consequence extremely rapid. The new principles were applied and exhibited by Mr. Hugh Powell and Mr. Andrew Ross with a degree of success which had never been anticipated; so perfect indeed were the corrections given to the achromatic object-glass—so completely were the errors of sphericity and dispersion balanced or destroyed—that the circumstance of covering the object with a plate of the thinnest glass or talc disturbed the corrections, if they had been adapted to an uncovered object, and rendered an object-glass which was perfect under one condition sensibly defective under the other.

This defect, if that should be called a defect which arose out of improvement, was first discovered by Mr. Ross, who immediately suggested the means of correcting it, and presented to the Society of Arts, in 1837, a paper on the subject, which was published in the 51st volume of their Transactions, and which, as it is, like Mr. Lister's, essential to a full understanding of the ultimate refinements of the instrument, we shall extract nearly in full.

"In the course of a practical investigation (says Mr. Ross) with the view of constructing a combination of lenses for the object-glass of a compound microscope, which should be free from the effects of aberration, both for central and oblique pencils of great angle, I combined the condition of the greatest possible distance between the object and object-glass; for in object-glasses of short focal length their closeness to the object has been an obstacle in many cases to the use of high magnifying powers, and is a constant source of inconvenience.

"In the improved combination, the diameter is only sufficient to admit the proper pencil; the convex lenses are wrought to an edge, and the concave have only sufficient thickness to support their figure; consequently, the combination is the thinnest possible, and it follows that there will be the greatest distance between the object and the object-glass. The focal length is $\frac{1}{8}$ of an inch, having an angular aperture of 60° , with a distance of $\frac{1}{25}$ of an inch, and a magnifying power of 970 times linear with perfect definition on the most difficult Podura scales. I have made object-glasses $\frac{1}{15}$ of an inch focal length; but as the angular aperture cannot be advantageously increased, if the greatest distance between the object and object-glass is preserved, their use will be very limited.

"The quality of the definition produced by an achromatic compound microscope will depend upon the accuracy with which the aberrations, both chromatic and spherical, are balanced, together with the general perfection of the workmanship. Now, in Wollaston's doublets, and Holland's triplets, there are no means of producing a balance of the aberrations, as they are composed of convex lenses only; therefore the best that can be done is to make the aberrations a minimum: the remaining positive aberration in these forms produces its peculiar effect upon objects (particularly the detail of the thin transparent class), which may lead to misapprehension of their true structure; but with the achromatic object-glass, where the aberrations are correctly balanced, the most minute parts of an object are accurately displayed, so that a satisfactory judgment of their character may be formed.

Fig. 15.

Fig. 16.

"It will be seen by *fig. 15*, that when a certain angular pencil AOA' proceeds from the object O , and is incident on the plane side of the first lens, if the combination is removed from the object, as in *fig. 16*, the extreme rays of the pencil impinge on the more marginal parts of the glass, and as the refractions are greater here, the aberrations will be greater also. Now, if two compound object-glasses have their aberrations balanced, one being situated as in *fig. 15*, and the other as in *fig. 16*, and the same disturbing power applied to both, that in which the angles of incidence and the aberrations are small will not be so much disturbed as where the angles are great, and where consequently the aberrations increase rapidly.

"When an object-glass has its aberrations balanced for viewing an opaque object, and it is required to examine that object by transmitted light, the correction will remain; but if it is necessary to immerse the object in a fluid, or to cover it with glass or talc, an aberration will arise from these circumstances, which will disturb the previous correction, and consequently deteriorate the definition; and this effect will be more obvious with the increase of the distance between the object and the object-glass.

Fig. 17.

"The aberration produced with diverging rays by a piece of flat and parallel glass, such as would be used for covering an object, is represented at *fig. 17*, where $GGGG$ is the refracting medium, or piece of glass covering the object O ; OP , the axis of the pencil, perpendicular to the flat surfaces; OT , a ray near the axis; and OT' , the extreme ray of the pencil incident on the under surface of the glass: then TR , $T'R'$, will be the directions of the rays in the medium, and RE , $R'E'$, those of the emergent rays. Now if the course of these rays is continued, as by the dotted lines, they will be found to intersect the axis at different distances, X and Y , from the surface of the glass; and the distance XY is the aberration produced by the medium which, as before stated, interferes with the previously balanced aberrations of the several lenses composing the object-glass. There are many cases of this, but the one here selected serves best to illustrate the principle. I need not encumber the description with the theoretical determination of this quantity, as it varies with exceedingly minute circumstances which we cannot accurately control; such as the distance of the object from the under side of the glass, and the slightest difference in the thickness of the glass itself; and if these data could be readily obtained, the knowledge would be of no utility in making the correction, that being wholly of a practical nature.

"If an object-glass is constructed as represented in *fig. 16*, where the posterior combination P and the middle M have together an excess of negative aberration, and if this be corrected by the anterior combination A , having an excess of positive aberration, then this latter combination can be made to act more or less powerfully upon P and M , by making it approach to or recede from them; for when the three are in close contact, the distance of the object from the object-glass is greatest; and consequently the rays from the object are diverging from a point at a greater distance than when the combinations are separated; and as a lens bends the rays more, or acts with greater effect, the more distant the object is from which the rays diverge, the effect of the anterior combination A upon the other two, P and M , will vary with its distance from thence. When, therefore, the correction of the whole is effected for an opaque object with a certain distance between the anterior and middle combination, if they are then put in contact, the distance between the object and object-glass will be increased: consequently the anterior combination will act more powerfully, and the whole will have an excess of positive aberration. Now the effect of the aberration produced by a piece of flat and parallel glass being of the negative character, it is obvious that the above considerations suggest the means of correction by moving the lenses nearer together, till the positive aberration thereby produced balances the negative aberration caused by the medium.

"The preceding refers only to the spherical aberration, but the effect of the chromatic is also seen when an object is covered with a piece of glass; for, in the course of my experiments, I observed that it produced a chromatic thickening of the outlines of the Podura and other delicate scales; and if diverging rays near the axis and at the margin are projected through a piece of flat parallel glass, with the various indices of refraction for the different colours, it will be seen that each ray will emerge separated into a beam consisting of the component colours of the ray, and that each beam is widely different in form. This difference, being magnified by the power of the microscope, readily accounts for the chromatic thickening of the outline just mentioned. Therefore, to obtain the finest definition of extremely delicate and minute objects, they should be viewed without a covering; if it be desirable to immerse them in a fluid, they should be covered with the

thinnest possible film of talc, as, from the character of the chromatic aberration, it will be seen that varying the distances of the combina-

Fig. 18.

tions will not sensibly affect the correction; though object-lenses may be made to include a given fluid or solid medium in their correction for colour.

Fig. 19.

"The mechanism for applying these principles to the correction of an object-glass under the various circumstances is represented in *fig. 18*, where the anterior lens is set in the end of a tube *A A*, which slides on the cylinder *B* containing the remainder of the combination; the tube *A A*, holding the lens nearest the object, may then be moved upon the cylinder *B*, for the purpose of varying the distance according to the thickness of the glass covering the object, by turning the screwed ring *C C*, or more simply by sliding the one on the other, and clamping them together when adjusted. An aperture is made in the tube *A*, within which is seen a mark engraved on the cylinder, and on the edge of which are two marks, a longer and a shorter, engraved upon the tube. When the mark on the cylinder coincides with the longer mark on the tube, the adjustment is perfect for an uncovered object; and when the coincidence is with the short mark, the proper distance is obtained to balance the aberrations produced by glass $\frac{1}{100}$ th of an inch thick, and such glass can be readily supplied.

"It is hardly necessary to observe, that the necessity for this correction is wholly independent of any particular construction of the object-glass; as in all cases where the object-glass is corrected for an object uncovered, any covering of glass will create a different value of aberration to the first lens, which previously balanced the aberration resulting from the rest of the lenses; and as this disturbance is effected at the first refraction, it is independent of the other part of the combination. The visibility of the effect depends on the distance of the object from the object-glass, the angle of the pencil transmitted, the focal length of the combination, the thickness of the glass covering the object, and the general perfection of the corrections for chromatism and the oblique pencils.

"With this adjusting object-glass, therefore, we can have the requisites of the greatest possible distance between the object and object-glass, an intense and sharply defined image throughout the field from the large pencil transmitted, and the accurate correction of the aberrations; also, by the adjustment, the means of preserving that correction under all the varied circumstances in which it may be necessary to place an object for the purpose of observation."

In the annexed engraving, *fig. 19*, we have shown the triple achromatic objective in connection with the eye-piece consisting of the field-glass *F F* and the

eye-glass *E E*, forming together the modern achromatic telescope. The course of the light is shown by drawing three rays from the centre and three from each end of the object *O*. These rays would, if left to themselves, form an image of the object at *A A*, but being bent and converged by the field-glass *F F*, they form the image at *B B*, where a stop is placed to intercept all light except what is required for the formation of the image. From *B B*, therefore, the rays proceed to the eye glass exactly as has been described in reference to the simple microscope and to the compound of two glasses.

If we stopped here we should convey a very imperfect idea of the beautiful series of corrections effected by the eye-piece, and which were first pointed out in detail in a paper on the subject published by Mr. Varley in the 51st volume of the 'Transactions of the Society of Arts.' The eye-piece in question was invented by Huyghens for telescopes, with no other view than that of diminishing the spherical aberration by producing the refractions at two glasses instead of one, and of increasing the field of view. It was reserved for Boscovich to point out that Huyghens had by this arrangement accidentally corrected a great part of the chromatic aberration; and this subject is further investigated with much skill in two papers by Professor Airy in the 'Cambridge Philosophical Transactions,' to which we refer the mathematical reader. These investigations apply chiefly to the telescope, where the small pencils of light and great distance of the object exclude considerations which become important in the microscope, and which are well pointed out in Mr. Varley's paper before mentioned.

Let *fig. 20* represent the Huyghenean eye-piece of a microscope; *F F*

Fig. 20.

and *E E* being the field-glass and eye-glass, and *L M N* the two extreme rays of each of the three pencils, emanating from the centre and ends of the object, of which, but for the field-glass, a series of coloured images would be formed from *R R* to *B B*; those near *R R* being red, those near *B B* blue, and the intermediate ones green, yellow, and so on, corresponding with the colours of the prismatic spectrum. This order of colours, it will be observed, is the reverse of that described in treating of the common compound microscope (*fig. 12*), in which the single object-glass projected the red image beyond the blue. The effect just described, of projecting the blue image beyond the red, is purposely produced for reasons presently to be given, and is called over-correcting the object-glass as to colour. It is to be observed, also, that the images *B B* and *R R* are curved in the wrong direction to be distinctly seen by a convex eye-lens, and this is a further defect of the compound microscope of two lenses. But the field-glass, at the same time that it bends the rays and converges them to foci at *B' B'* and *R' R'*, also reverses the curvature of the images as there shown, and gives them the form best adapted for distinct vision by the eye-glass *E E*. The field-glass has at the same time brought the blue and red images closer together, so that they are adapted to pass uncoloured through the eye-glass. To render this important point more intelligible, let it be supposed that the objective had not been over-corrected, that it had been perfectly achromatic; the rays would then have become coloured as soon as they had passed the field-glass; the blue rays, to take the central pencil for example, would converge at *b* and the red rays at *r*, which is just the reverse of what the eye-lens requires; for as its blue focus is also shorter than its red, it would demand rather that the blue image should be at *r* and the red at *b*. This effect we have shown to be produced by the over-correction of the objective, which protrudes

the blue foci $B B$ as much beyond the red foci $R R$ as the sum of the distances between the red and blue foci of the field-lens and eye-lens; so that the separation $B R$ is exactly taken up in passing through those two lenses, and the whole of the colours coincide as to focal distance as soon as the rays have passed the eye-lens. But while they coincide as to distance, they differ in another respect; the blue images are rendered smaller than the red by the superior refractive power of the field-glass upon the blue rays. In tracing the pencil L , for instance, it will be noticed that after passing the field-glass two sets of lines are drawn, one whole and one dotted, the former representing the red, and the latter the blue rays. This is the accidental effect in the Huyghenian eye-piece pointed out by Boscovich. This separation into colours at the field-glass is like the over-correction of the objective; it leads to a subsequent complete correction. For if the differently coloured rays were kept together till they reached the eye-glass, they would then become coloured, and present coloured images to the eye; but fortunately, and most beautifully, the separation effected by the field-glass causes the blue rays to fall so much nearer the centre of the eye-glass, where, owing to the spherical figure, the refractive power is less than at the margin, that the spherical error of the eye-lens constitutes a nearly perfect balance to the chromatic dispersion of the field-lens, and the red and blue rays L' and L'' emerge sensibly parallel, presenting, in consequence, the perfect definition of a single point to the eye. The same reasoning is true of the intermediate colours and of the other pencils.

From what has been stated, it is obvious that we mean by an achromatic objective one in which the usual order of dispersion is so far reversed, that the light, after undergoing the singularly beautiful series of changes effected by the eye-piece, shall come uncoloured to the eye. We can give no specific rules for producing these results. Close study of the formulæ for achromatism given by the celebrated mathematicians we have quoted will do much, but the principles must be brought to the test of repeated experiment. Nor will the experiments be worth anything unless the curves be most accurately measured and worked, and the lenses centred and adjusted with a degree of precision which, to those who are familiar only with telescopes, will be quite unprecedented.

The Huyghenian eye-piece which we have described is the best for merely optical purposes; but when it is required to measure the magnified image, we use the eye-piece invented by Mr. Ramsden, and called, from its purpose, the micrometer eye-piece. When it is stated that we sometimes require to measure portions of animal or vegetable matter a hundred times smaller than any divisions than can be artificially made on any measuring instrument, the advantage of applying the scale to the magnified image will be obvious, as compared with the application of engraved or mechanical micrometers to the stage of the instrument.

The arrangement is shown in *fig. 21*, where EE and FF are the eye- and field-glass, the latter having now its plane face towards the object. The rays from the object are here made to converge at $A A$, immediately in front of the field-glass, and here also is placed a plane glass on which are engraved divisions of $\frac{1}{100}$ th of an inch or less. The markings of these divisions come into focus therefore at the same time as the image of the object, and both are distinctly seen together. Thus the measure of the magnified image is given by mere inspection, and the value of such measures in reference to the real object may be obtained thus, which, when once obtained, is constant for the same objective. Place on the stage of the instrument a divided scale the value of which is known, and, viewing this scale as the microscopic object, observe how many of the divisions on the scale attached to the eye-piece correspond with one of those in the magnified image. If, for instance, ten of those in the eye-piece correspond with one of those in the image, and if the divisions are known to be equal, then the image is ten times larger than the object, and the dimensions of the object are ten times less than indicated by the micrometer. If the divisions on the micrometer and on the magnified scale

were not equal, it becomes a mere rule-of-three sum; but in general this trouble is taken by the maker of the instrument, who furnishes a table showing the value of each division of the micrometer for every objective with which it may be used.

While on the subject of measuring it may be well to explain the mode of ascertaining the magnifying power of the compound microscope, which is generally taken on the assumption before mentioned, that the naked eye sees most distinctly at the distance of 10 inches.

Place on the stage of the instrument, as before, a known divided

scale, and when it is distinctly seen, hold a rule at 10 inches distance from the disengaged eye, so that it may be seen by that eye, overlapping or lying by side of the magnified picture of the other scale. Then move the rule till one or more of its known divisions correspond with a number of those in the magnified scale, and a comparison of the two gives the magnifying power.

Having now explained the optical principles of the achromatic compound microscope, it remains only to describe the mechanical arrangements for giving those principles their full effect. The mechanism of a microscope is of much more importance than might be imagined by those who have not studied the subject. In the first place, steadiness, or freedom from vibration, and most particularly freedom from any vibrations which are not equally communicated to the object under examination, and to the lenses by which it is viewed, is a point of the utmost consequence. When, for instance, the body containing the lenses is screwed by its lower extremity to a horizontal arm, we have one of the most vibratory forms conceivable; it is precisely the form of the inverted pendulum, which is expressly contrived to indicate otherwise insensible variations. The tremor necessarily attendant on such an arrangement is magnified by the whole power of the instrument; and as the object on the stage partakes of this tremor in a comparatively insensible degree, the image is seen to oscillate so rapidly, as in some cases to be wholly undistinguishable. Such microscopes cannot possibly be used with high powers in ordinary houses abutting on any paved streets through which carriages are passing, nor indeed are they adapted to be used in houses in which the ordinary internal sources of shaking exist.

One of the best modes of mounting a compound microscope is shown in the annexed view (*fig. 22*), which, though too small to

Fig. 22.—Ross's Microscope.

exhibit all the details, will serve to explain the chief features of the arrangement.

$A A$ are two uprights surmounting the tripod base, $B B B$. At c is the axis upon which the instrument turns, and by which any inclination, from vertical to horizontal, may be given to it, in which position it may be clamped by the small handle d when the use of over-balancing apparatus on the secondary stage renders this necessary. Motion is given to the bar e by the milled head f : a corresponding milled head on the other side of the instrument may also be used for the same purpose. At the end of the arm $g g$ is fixed the compound tube $h g i$, which receives at its upper extremity the eye-piece j : at its lower

extremity, I, the objective is to be screwed on. K L M, is the mechanical stage upon which the objects under microscopic examination are placed, the milled head marked K giving it a vertical motion, and that marked L a lateral one. This stage has also a rotary motion, concentric with the axis of the compound tube H G I, which enables the observer to examine an object in any position of rotation, keeping the object in the field of view. Fitted to the secondary stage, N, is represented a system of diaphragms employed to regulate the diameter of the pencil of light reflected from either the plane or concave surface of the mirror O. The diaphragms can be removed, and a variety of apparatus substituted. The regulation of the distance between the illuminator and the object under examination is effected by means of the milled head P. Q is one of two milled heads which give motion in rectangular directions to the secondary stage, for the purpose of causing its axis to coincide with that of the compound tube. The milled head marked R communicates a rotary motion to the tube of the secondary stage. In using the higher powers, the instrument is only approximately adjusted by the milled head R, the rack with which it communicates being called the coarse adjustment: the fine adjustment is effected by means of the graduated milled head S, which is connected with a screw and lever acting on the optical arrangement $\frac{1}{300}$ of an inch for each revolution of the milled head S. The milled head T is used to clamp the arm to the bar of the instrument. This description though brief, will be found sufficiently lucid to convey to the mind of the reader correct notions of the mechanical arrangements of the compound microscope.

Most of the directions for viewing and illuminating objects, given in reference to the simple microscope, are applicable to the compound. An Argand lamp placed in the focus of a large detached lens so as to throw parallel rays upon the mirror, is the best artificial light; and for opaque objects the light so thrown up may be reflected by metallic specula (called, from their inventor, Lieberkhuns) attached to the object-glasses.

On the proposal of Sir David Brewster and M. Dujardin, the Wollaston condenser was achromatised with very excellent effect by constructing it with three pair of achromatic lenses, instead of the single lens before described. Subsequent improvements have been effected by Mr. Gillett, and a modification of the form adopted by that gentleman has been constructed by Messrs. Powell and Lealand. Other modes of illumination have also been adopted, such as the prisms of Amici, Nachet, and Powell, Nobert's circular condenser, Ross's spotted lens for dark ground illumination, &c.

The erector commonly applied to the compound microscope consists of a pair of lenses acting like the erecting eye-piece of the telescope. But this, though it is convenient for the purpose of dissection, very much impairs the optical performance of the instrument.

For drawing the images presented by the microscope, the best apparatus consists of a mirror M (Fig. 23), composed of a thin piece of rather dark-coloured glass, cemented on to a piece of plate-glass inclined at an angle of 45° in front of the eye-glass E. The light escaping from the eye-glass is assisted in its reflection upwards to the eye by the dark glass, which effects the further useful purpose of rendering the paper less brilliant, and thus enabling the eye better to see the reflected image. The lens L, below the reflector, is to cause the light from the paper and pencil to diverge from the same distance as that received from the eye-glass; in other words, to cause it to reach the

Fig. 23.

eye in parallel lines.

Dr. Wollaston's Camera Lucida, as shown in Fig. 24, is sometimes attached to the eye-piece of the microscope for the same purpose. In this instrument the rays suffer two internal reflections within the glass prism, as will be seen explained in the article CAMERA LUCIDA. In this minute figure we have omitted to trace the reflected rays, merely to avoid confusion.

Fig. 24.

Of late years, the microscopist has availed himself of markings on the frustules of the diatomaceæ as tests for the separating power of his objectives: for a description of these tests we must refer the reader to Smith's 'Diatomaceæ.' Although many objectives possessing large angles of aperture are capable of discovering markings upon diatomæ, yet, for definition, the employment of a well-marked scale of Podura is advisable. When circumstances admit of it, opticians test their objectives by means of a disc of light reflected from a small globule of mercury; this test, however, can be depended upon only when employed by the practised and skilful optician, great experience being required to judge of an objective by this means.

For a full description of the nature and uses of the numerous adjuncts to the microscope, we must refer the reader to the valuable works of Quekett, Hogg, and Beale, on that subject.

Although the reflecting microscope is now very little used, it may be expected that we should mention it. In this instrument, at Fig. 25,

the object O is reflected by the inclined face of the mirror M, and the rays are again reflected and converged by the ellipsoidal reflector R R,

Fig. 25.

which effects the same purpose as the object-glass of the compound microscope. It forms an image which is not susceptible of the over-correction as to colour before described, and which therefore becomes coloured in passing through the eye-piece. This fact, and the loss of light by reflection, will probably always render the reflecting microscope inferior to the achromatic refracting.

The *Lucernal Microscope* is a hollow pyramidal box, of wood, at the smaller extremity of which is a tube carrying the usual system of lenses for magnifying objects. At the larger end, which is towards the observer, there are two lenses in frames; their axes, as well as those of the small lenses at the opposite extremity, being coincident with the axis of the box; and between the exterior of the two lenses and the eye of the observer there is usually placed a plate of glass, rough-ground on one side, which serves as a screen to receive the rays of light proceeding from the object whose representation is to be viewed: the object is fixed in a small frame, as usual, and is placed in a groove made for the purpose immediately beyond the tube containing the system of lenses, at the small end of the pyramidal box.

This box, the axis of which is in a horizontal position, is mounted on a brass stand, which may be placed on the floor or on a table, and the parts of the apparatus are capable of being correctly adjusted by means of screws. The instrument was invented by Mr. George Adams, a distinguished optician in London, and it received its name from the images of the objects being projected on the ground-glass screen by the rays of light transmitted from a lamp through the lenses, the observations being made by night or in a darkened room.

The correct definition of the image depends upon the achromatism of the lenses at the object end of the instrument, a subject which has been treated in the previous part of this article: and therefore it will be sufficient to notice here only the means employed to enlighten the field of view.

For this purpose, in general, an Argand lamp is placed beyond the object, with respect to the microscope; or, if thought necessary, two or more such lamps may be so situated: the light, after passing through a hemisphere of glass, is, when an opaque object is to be viewed, made to fall in a convergent state upon a small concave mirror, which is so inclined as to reflect the light back upon the object; and from the different points on the surface of the latter the pencils of rays proceed through the object-lenses and the box to the glass screen.

By the refraction of the light in passing through the lenses a highly magnified image of the object is formed; and several persons may then place themselves so as to see the image on the screen at the same time; or, by placing the eye at a small aperture in the produced axis of the instrument, one person may, with a pencil, draw on the glass, or on tracing-paper laid over it, the figure of the object; it being understood that, by means of the proper adjusting-screws, the rays in each pencil are made to unite accurately in one point on the screen.

When the object to be viewed is transparent, the light is made to fall in a condensed state upon it, after having been transmitted through a convex lens, or two such; and, from the object, the rays proceed as before to the screen through the system of lenses which constitute the compound objective of the microscope, and through those at the opposite extremity of the box.

Instead of having a plate of ground-glass to receive the image, the pencils of light from the object, after passing through the lenses, may be allowed to fall on a board painted white or covered with white paper; the distance of the board from the instrument (about 6 or 8 feet) being such that the rays in each pencil may converge to a point upon it: thus there will be obtained a greatly magnified image of the object, which may be observed by many spectators at one time. Such a screen should have the form of a segment of a hollow sphere, the light being received on its concave surface; for by that construction the image will be nearly equally distinct at the centre and about the margin.

The *Solar Microscope*, which was invented by Dr. Lieberkhun, in 1738, produces a greatly magnified image of a small object in a similar manner by means of the sun's light. It consists of a conical tube fixed by its base to a frame of wood; the latter being screwed to a closed window-shutter at an aperture purposely made in the latter: the tube projects into the room, which, when the observations are to be made, is rendered quite dark, and is sometimes lined with black cloth. The magnifying power is produced by a system of lenses contained in the tube, as in other microscopes. On the exterior of the window is a frame carrying a rectangular piece of looking-glass; this frame is attached by a joint at one of its sides to a ring of wood or brass which is made

to surround the aperture in the shutter. The mirror, by turning on the hinge, is capable of being fixed at any angle with the wall of the building; while the ring to which it is attached can, by means of a rack and pinion, be made to turn on the horizontal axis of the instrument, so as to permit the rays of the sun, whatever be the position of the latter, to be reflected into the tube. By means of lenses disposed for the purpose, these rays are made to converge on the object; and from thence after refraction through the system of object-glasses, they proceed to a screen on which they depict the magnified image.

When the object is transparent, the rays of solar light are allowed to pass from the mirror directly through the lenses to the screen; but when it is opaque, a convex lens placed at the aperture in the window-shutter causes the solar rays to condense on a small mirror placed in a box at that end of the instrument which is within the room, and from this mirror the rays are reflected to the object. The condensed light thus thrown on the object diverges from thence and passes through the system of lenses, by refraction in which the magnifying power is produced; these lenses being placed in a tube which, as well as the object, is within the box containing the mirror last mentioned, but a little above the latter, so that the rays of light proceeding from the object to the magnifying lenses may not be intercepted.

The mirror by which the sun's light is reflected into the instrument is sometimes connected with a clockwork apparatus, by which its position is continually varied correspondently to the apparent change of the sun's place; and thus the reflected light is made constantly to pass through the tube. [HELIOSTAT.]

Sir David Brewster has given, in his 'Treatise on New Philosophical Instruments,' p. 405, &c., a method of preparing objects of natural history for observation by the microscope, that their parts may preserve their proper shape and colour, and thus be seen to the greatest advantage.

In the oxy-hydrogen microscope which is now more generally used, the chief effect is to throw an intense light upon the object, which is sometimes done by mirrors, and sometimes by lenses.

In Fig. 26, L represents the cylinder of burning lime, R R the reflector,

which concentrates the light upon the object O O; the rays from which, passing through the two plano-convex lenses, are brought to foci upon a screen placed at a great distance, and upon which is formed the magnified image.

Fig. 27 shows a combination of lenses to condense the light upon the

object. In either case the optical arrangements by which the image is formed admit of the same perfection as those which have been described for the compound microscopes. A few achromatic glasses for oxy-hydrogen microscopes have been made, and they will ultimately become valuable instruments for illustrating lectures on natural history and physiology. One made by Mr. Ross was exhibited a few years ago at the Society of Arts to illustrate a lecture on the physiology of woods. It should be observed however that both the oxy-hydrogen and solar microscopes require either a spherical screen, or that the objects should be mounted between spherical glasses, in order to bring the whole into focus at one time. This latter plan was adopted on the occasion just mentioned with perfect success.

MICROSCOPIUM (the Microscope), a constellation of Lacaille, situated above Grus and Indus, at the junction of Capricornus and Sagittarius. The only star in it worth notice is α , of the $4\frac{1}{2}$ magnitude, (307) in the catalogue of Piazzi.

MIDDLE LATITUDE SAILING. [SAILING.]

MIDDLE VOICE is a term employed in Greek grammar to indicate a class of verbs which are called reflective in some other languages. The reflective meaning is supposed to be the original and main signification of the middle voice, but it is difficult in many of the middle verbs in Greek to trace the reflective notion. Although a separate voice, that is, a distinct mode of conjugation, has been assigned to verbs with a middle signification, there are only two tenses in the Greek verb which have a form peculiar to the middle notion, namely, the first and second aorists in $\sigma\alpha\mu\eta\nu$ and $\sigma\eta\mu\eta\nu$; which in the model verb, are $\acute{\epsilon}\tau\upsilon\psi\acute{\alpha}\mu\eta\nu$ and

$\acute{\epsilon}\tau\upsilon\psi\acute{\alpha}\mu\eta\nu$. There are four tenses peculiar to the passive signification, namely, the two futures in $\theta\eta\sigma\omicron\mu\alpha\iota$ and $\eta\sigma\omicron\mu\alpha\iota$, and the two aorists in $\theta\eta\nu$ and $\eta\nu$ ($\tau\upsilon\phi\text{-}\theta\eta\sigma\omicron\mu\alpha\iota$, $\tau\upsilon\phi\text{-}\eta\sigma\omicron\mu\alpha\iota$, $\acute{\epsilon}\tau\upsilon\phi\text{-}\theta\eta\nu$, $\acute{\epsilon}\tau\upsilon\phi\text{-}\eta\nu$). The future in $\sigma\omicron\mu\alpha\iota$ ($\tau\upsilon\phi\text{-}\sigma\omicron\mu\alpha\iota$, $\lambda\acute{\epsilon}\gamma\text{-}\sigma\omicron\mu\alpha\iota$), which is called in most grammars the future middle, has a passive signification, as well as a middle. (Monk on Eurip. 'Hippol.' l. 1458; 'Quarterly Journal of Education,' vol. iv. p. 158.) The following table will make the matter clearer:—

Tenses common to the passive and middle significations.

Present	$\tau\acute{\upsilon}\pi\tau\omicron\mu\alpha\iota$.	Perfect	$\tau\acute{\epsilon}\tau\upsilon\mu\mu\alpha\iota$.
Imperfect	$\acute{\epsilon}\tau\upsilon\pi\tau\acute{\omicron}\mu\eta\nu$.	Past Perfect	$\acute{\epsilon}\tau\epsilon\tau\acute{\upsilon}\mu\mu\eta\nu$.
Future	$\tau\acute{\upsilon}\psi\omicron\mu\alpha\iota$.	Future Perfect	$\tau\epsilon\tau\acute{\upsilon}\psi\omicron\mu\alpha\iota$.

Tenses peculiar to the middle signification.

1st Aorist	$\acute{\epsilon}\tau\upsilon\psi\acute{\alpha}\mu\eta\nu$.	2nd Aorist	$\acute{\epsilon}\tau\upsilon\psi\acute{\omicron}\mu\eta\nu$.
------------	--	------------	--

Tenses peculiar to the passive signification.

1st Aorist	$\acute{\epsilon}\tau\upsilon\phi\theta\eta\nu$.	2nd Aorist	$\acute{\epsilon}\tau\upsilon\phi\eta\nu$.
1st Future	$\tau\upsilon\phi\theta\eta\sigma\omicron\mu\alpha\iota$.	2nd Future	$\tau\upsilon\phi\eta\sigma\omicron\mu\alpha\iota$.

Since then so many tenses in the Greek verb have the same form both for the middle and passive signification, it becomes an interesting object of inquiry, whether we should assign the priority to the passive or middle notion. This question has usually been answered by grammarians in favour of the passive; but the comparison of other languages etymologically connected with the Greek, would lead us to a contrary supposition. Very few of the Indo-Germanic languages have a form peculiar to the passive signification; even in Sanskrit the passive verb is not considered by Hindu grammarians as a distinct voice, but is classed among the derivative verbs. There are however two voices in the Sanskrit verb, answering to the Greek active and middle, which are called respectively *parasmaipadam* and *atmanepadam*; the former answering to the active in Greek, and the latter having generally a reflective or medial but never a passive signification. The tenses of the passive verb are formed by prefixing the syllable *ya* to the person endings of the *atmanepadam* conjugation. These person endings are evidently the same as those of the middle voice in Greek, as the following table of the present tense will show:—

	Sanskrit.	Greek.
Singular.	{ kship-ê	$\tau\acute{\upsilon}\pi\tau\text{-}\omicron$, $\mu\alpha\iota$.
	{ kship-a, sê	$\tau\acute{\upsilon}\pi\tau\text{-}\epsilon$, $\sigma\alpha\iota$ (afterwards $\tau\acute{\upsilon}\pi\tau\text{-}\epsilon\alpha\iota = \tau\acute{\upsilon}\pi\tau\text{-}\eta$).
	{ kship-a, tê	$\tau\acute{\upsilon}\pi\tau\text{-}\epsilon$, $\tau\alpha\iota$.
Dual.	{ kship-â, vahê	$\tau\upsilon\pi\tau\text{-}\acute{\omicron}$, $\mu\epsilon\theta\omicron\nu$.
	{ kship-ê, thê	$\tau\acute{\upsilon}\pi\tau\text{-}\epsilon$, $\sigma\theta\omicron\nu$.
	{ kship-êtê	$\tau\acute{\upsilon}\pi\tau\text{-}\epsilon$, $\sigma\theta\omicron\nu$.
Plural.	{ kship-â, mahê	$\tau\upsilon\pi\tau\text{-}\acute{\omicron}$, $\mu\epsilon\theta\alpha$.
	{ kship-a, dhê	$\tau\acute{\upsilon}\pi\tau\text{-}\epsilon$, $\sigma\theta\epsilon$.
	{ kship-a, ntê	$\tau\acute{\upsilon}\pi\tau\text{-}\omicron$, $\nu\tau\alpha\iota$.

That the passive signification should in course of time have taken the place of the middle, will not appear surprising, when it is recollected that a reflective verb is actually used in many languages, where a passive is used in others to express the same thing. An instance occurs in such a phrase as *les bas se vendent ici*, stockings sell themselves here; and in the same manner in Italian we have such phrases as *si dicono molte cose*, many things say themselves, or are said; *si loda l'uomo modesto*, a modest man praises himself, that is, is praised; *mi si domanda uno scudo*, a dollar demands itself of me, that is, is demanded of me. The same idiom occurs both in Spanish and Portuguese.

It has been the practice to deny to the Latin language the possession of a middle, except in the case of deponent verbs. But in such a phrase as *Rhenus Oceano miscetur*, the verb is rather of the middle than the passive character, and this certainly must be allowed when it is said of a soldier *induitur galeam*, or when a general *milites armari jubet*; or as in the line of Virgil ('Georg.' iii. 219)—

Pascitur in magna sylva formosa juvenca.

The above explanation of the middle form or voice is one which has been proposed; still the matter may require further discussion. The truth is, that the classification of verbs into active and passive, or into active, passive and middle, is a very imperfect one, and for the purposes of a philosophical exhibition of grammar a new classification is wanting. The expressions "I walk," "I eat," &c., are in signification allied to the middle voice, though the form of these words does not differ from the form "I kill," "I cut," &c. In order to express the notion of the person "I" being "killed," some modification of the primitive form "kill" must be made, and another modification may be necessary to express the act of "self-killing." Thus in French we have *il tue*, *il fut tué*, and *il s'est tué*. In the last instance the act of "self-killing" is distinguished from the act of "being killed" by the addition of a word. In the Greek language the present tense of the passive form may be used to express either the act of the person being killed, or killing himself. In the first and second aorist tenses a peculiar form is used to express the act of self-killing; but as this peculiar form has the characteristic termination of what is called a passive verb, and not of an active, it might be classed under the passive voice

as a peculiar tense, and the term middle voice might be got rid of altogether.

MIDHEAVEN (Astronomy), a technical term for the point of the ecliptic which is on the meridian at any given moment.

MIDIANITES (מִדְיָנִים, *Maḏiānīṭai*, *Maḏiynāioi*), the descendants of Midian, the son of Abraham by Keturah (Gen. xxv. 2, 4), who, with the other sons of Abraham's concubines, migrated eastward from Canaan during Abraham's life (Gen. xxv. 6). In the time of Jacob their merchants had caravans from Gilead through Palestine to Egypt (Gen. xxxvii. 28, 36). In the time of Moses we find them in Arabia Petrea, under the government of a high-priest (Exod. ii. 15), and leading their flocks as far as Mount Sinai (Exod. iii. 1); but they did not extend to the west of this mountain, for the Israelites did not come in contact with them in their march from Egypt, but, on the contrary, Jethro, their high-priest, came out of his country to visit Moses, when the Israelites were encamped at the foot of Sinai (Exod. xviii. 1-5; Numb. x. 29). They subsequently frequently harassed the Israelites till Gideon defeated them and the Amalekites in the plain of Jezreel, and pursued them beyond the Jordan. They were still known, however, in the time of Isaiah (lx. 6) as a commercial tribe.

The exact country of the Midianites is not determined with certainty. Some, indeed, suppose that those in Arabia Petrea, mentioned in Exodus (ii. 15) were quite a different nation from those on the east of Palestine, the former being related to the descendants of Cush, the son of Ham (Numb. xii. 1; Hab. iii. 7). But the more common and more probable opinion is, that the Midianites were all descended from the same stock, and those on the Ælanitic Gulf were sometimes called Ethiopians, while those near the Dead Sea are occasionally called Ishmaelites; and there may have been other bodies of them in the western part of Arabia (1 Kings, xi. 18). The Arabian geographers Abulfeda and Edrisi mention a town, Madian, on the eastern side of the Ælanitic Gulf of the Red Sea, somewhat to the north of the modern Moilah, which is probably the *Mīdiāna* of Ptolemy (v. 17) and the *Maḏiānā* of Josephus ('Ant.' xii. 11, 1), and of which the ruins were to be seen in the time of Eusebius and Jerome.

The Midianites were governed by their elders (Numb. xxii. 4), and by chiefs or kings (Numb. xxv. 15, 18; xxxi. 8; Judges, vii. 25; viii. 3, 5). They possessed many camels, and had acquired great wealth, probably by commerce (Judges, vi. 5; vii. 12; viii. 10, 24; Is. lx. 6). Their religion was the worship of Baal-peor.

MIDSHIPMEN are young gentlemen ranking as intermediate between 1st class petty officers and warrant officers on board a ship of war. Their duty is to pass to the seamen the orders of the captain or other superior officer, and to superintend the performance of the duties so commanded. They are educated for their profession at the Royal Naval College, and commence their career in the service as naval cadets between the ages of 12 and 14. The whole system of entering, educating, and promoting junior officers in the navy has recently undergone complete revision. To qualify them for promotion as lieutenants, they must be able to pass a proper examination in seamanship and navigation, be of the full age of 19, and have passed a period of 5½ years in her Majesty's navy.

The monthly pay of an officer of this class is 2*l.* 14*s.* 3*d.* in ships of all rates.

MIDSUMMER EVE. On the eve of the feast of the Nativity of St. John the Baptist, or Midsummer-day, it was long the custom in England to kindle fires at midnight, sometimes upon the hills, in honour of the summer solstice; a practice which Gebelin, in his 'Allegories Orientales,' says was followed among the ancient nations. The same practice has prevailed in many other countries, accompanied with superstitious observances, evidently the relics of some very ancient time, and now generally fallen into desuetude. (Brand's *Popular Antiquities*, Sir H. Ellis's edit., vol. i., 1841.)

MIGNONETTE (*Reseda odorata*) is a common garden flower, with lanceolate bluntish entire or trifid leaves, and a 6-parted calyx equal in length to the petals, which are finely cleft into many club-shaped divisions, the two lowest simple, the capsules 3-toothed. It is a native of the north of Africa and Egypt, but its delicious fragrance has caused it to be cultivated all over the world. It is naturally an herb, but when trained in the greenhouse it becomes shrubby. This plant is in great demand in the London markets, and is very extensively cultivated. The seeds should be sown in the ground in April, on a bed well manured with rotten dung. As the plants rise they should be thinned by degrees, so as to leave them from 9 to 12 inches apart. They must be well watered, and require abundance of sun and air. Before they come into bloom nip off the centre shoots, after which the side shoots will fill the vacant spaces, and form a full and very pretty bed. If sown in pots or boxes, a mixture of rotten turf and cow-dung, of which the larger portion should be of the turf, must be placed for the reception of the seed, and the plants should be treated as above. Transplanting seldom succeeds. This is the common garden culture, and the plants flower in June. In a forced culture, for flowering from December to February, a sowing should be made in July, in the open ground, and the plants potted in September and removed in-doors. The crop for March, April, and May should be sown in pots not later than the 25th of August. The plants from this sowing will not suffer from exposure to rain whilst they are young; they must however be protected from

early frosts, and are to be thinned in November. At the same time the pots should be sunk 3 or 4 inches in some old tan or coal-ashes and should be covered with a frame, which it is best to place fronting the west, for then the lights may be left open in the evening, to catch the sun whenever it sets clear. The third or spring crop should be sown in pots not later than the 25th of February. These must be placed in a frame on a gentle heat; and as the heat declines, the pots must be let down 3 or 4 inches into the dung-bed, which will keep the roots moist, and prevent their leaves turning brown from the heat of the sun in April and May. The plants thus obtained will be in perfection by the end of May.

The arborescent plant is often called Tree-Mignonette. It may be propagated by seeds or by cuttings, which readily strike root. The young plants should be potted singly, and brought forward by heat. As they grow they should be tied to a stick, and all side shoots should be pinched off. As the plants attain a greater size they should be shifted progressively into larger pots.

MILE. This word is derived from *miliare*, the *mille passus*, or thousand paces, of the Romans. Each pace was 5 feet, and each foot certainly contained between 11·60 and 11·64 modern English inches. [WEIGHTS AND MEASURES.] Taking the Roman foot at 11·62 English inches, the original Roman mile was therefore 1614 yards, or nine-tenths and one-sixtieth of an English statute mile, very nearly; while the English mile is a Roman mile and nine-hundredths of a Roman mile, very nearly.

The English statute mile is 8 furlongs, each of 220 yards, or 40 poles of 5½ yards or 16½ feet each. It is also 80 surveying chains of 22 yards each. It is therefore 1760 yards, or 5280 feet. The square mile is 6400 square chains, or 640 acres.

The remains of the Roman mile and the Gallic or Celtic league [LEAGUE] are found in the itinerary measures of most European countries. The following list (taken from Kelly's 'Cambist,' except the statement of the Roman mile) will show the itinerary measures of various countries, as they are usually reputed in English yards and statute miles. We have placed them in order of magnitude. The last column shows in round numbers how many of each make 1000 statute miles:—

Yards.		Stat. miles.	No. in 1000 stat. miles.
1614	Ancient Roman mile	·917	1091
1628	Modern Roman mile	·925	1081
1760	English statute mile	1·000	1000
1808	Tuscan mile	1·027	974
1984	Ancient Scottish mile	1·127	887
2240	Irish mile	1·273	786
4263	French posting league	2·422	413
4635	Spanish judicial league	2·634	380
4860	French league of 25 to the degree	2·761	362
6760	Portugal league	3·841	260
6859	German short mile	3·897	257
6864	Flanders league	3·900	256
7416	Spanish common league	4·214	237
8237	Prussian mile	4·680	214
8244	Danish mile	4·684	213
8475	Dantzic mile	4·815	205
9113	Hungarian mile	5·178	193
9153	Swiss mile	5·201	192
10126	German long mile	5·753	174
11559	Hanoverian mile	6·568	152
11700	Swedish mile	6·648	150

The metrical mile of 1000 French metres, or one kilometre, or 1093 English yards, is put down among the measures of France, Italy, and the Netherlands; the geographical mile, or the sixtieth of a degree of latitude, or about 2025 yards, is used in England and Italy; the geographical league of three such miles, or 6075 yards, is used in England and France; the German geographical mile is four English geographical miles, or 8100 yards; the short mile used in Poland (which is also the league of Brabant) is the geographical league (6076 yards), and the long mile of the same country is the German geographical mile (8101 yards), which is also the length of the mile in Holland. The Arabian mile is 2148 yards; the Chinese li 632 yards; the Persian parasang 6086 yards; the Russian werst 1167 yards; and the Turkish berri 1826 yards. All the preceding statements relative to modern measures rest on the authority of the work cited.

This diversity of itinerary measures, particularly as observable in countries which were formerly under Roman sway, can only be conjecturally explained; partly by supposing that the mile (Roman) and the league (Celtic) were in process of time confounded with each other (as Ingulphus asserts to have been the case in England), partly by recurring to the well-known tendency to give the same name to measures which were multiples one of the other. [LEAGUE.] It would be much beyond us to attempt any derivation of the preceding anomalous measures, either from the mile or the league, and we shall in the present article confine ourselves to the history of the English mile.

It will be necessary to treat this subject at some length, on account of the manner in which our metrologists and antiquaries have passed it over. The legal history is simply this; that previously to the reign of Elizabeth the statutes on weights and

measures confined themselves entirely to the regulation of the smaller standards; while in the 35th year of that queen an act was passed which (perhaps undesignedly on the part of its framers) has fixed the mile at its present length. This statute, though it is always appealed to as if made for the purpose of settling the question, yet in fact does nothing more than incidentally define a mile for a particular purpose. Persons are forbidden to build within three miles of London, and the mile is to be 8 furlongs of 40 perches of 16½ feet each. But whether this mile had become common, and only wanted the sanction of law, whether it was a new measure intended to be generally enforced, or whether it was meant as the measure for the particular purpose indicated, and for that purpose only, cannot be gathered, at least from the recital in the Statutes at large. It will however subsequently appear that we are not without something like a probable account of the derivation of the measure; and whatever doubt may rest upon the meaning of the statute, it was considered by an authority of the reign of James I. (Cowell) as a general declaration of the length of the mile. Previously however to the act of Elizabeth it may be doubted whether any uniform mile was in existence. Most unquestionably many, perhaps most, writers made use of a mile of 5000 feet, probably not being aware of the English foot having become longer than the Roman, and intending to use the Roman mile. (See the citations in LEAGUE.) Thus, Roger Bacon, in his general description of the earth, follows (except as hereinafter mentioned) the Latin writers, and uses their mile as a matter of course, without the least warning of his being aware that he was using a measure [different from the popular one of his time. Accordingly, in a writer on any mathematical or cosmographical topic the mile may be presumed to have 5000 feet. If however the subject had any connection with astronomy, and if Arabian writers were referred to, it was not unusual to use the Arabian mile of 2000 yards (according to Roger Bacon's estimation, Jebb, p. 141).

If, as we believe we shall presently show, a longer mile were in popular use, it may be doubted whether the authors above alluded to were aware of the difference. They certainly did not perpetuate such knowledge; for Dr. Bernard, the most profound of English metrologists, found the mile of 5000 feet sufficiently common in old writings to induce him to give it a name, and call it the English *geometrical* mile, meaning, we suppose, that principally used in mathematical writings; but he does not give the least hint that any other mile, except this geometrical mile and the statute mile, was ever in existence. Nor does his predecessor Greaves, when he remarks that great differences have been observed between measured and statute miles, hint at such discordances being derived from the remains of any old and different measure, or at any acknowledged measure different from the statute mile. This mile of 5000 feet continued in use among seamen, whose measures depend more upon writers on navigation than on acts of parliament, until the earth's dimensions became better known. A very old notion as to the earth's magnitude gave 60, or at most 62½, Roman miles to the degree. The sea mile tallied with that of writers on shore, until the measures of Picard, &c., became well known; but the sixtieth part of a degree of latitude is so convenient a standard measure for the sailor, that under the name of a nautical or geographical mile it has lengthened with the common estimation of the degree of latitude. Thus, in the time of Gunter we find the degree described as 60 miles of 5000 feet each; though he certainly says (*On the Cross-Staffe*, b. xi., cap. 6), that by comparison of observations,* he thinks 352,000 feet nearer the truth. Even almost as late as the Revolution some common works written for landmen describe the sea league as three Italian miles, which answers nearly to 15,000 feet. By the time of Dr. Bernard however we find the sea mile described as coinciding with the statute mile (*De Mens. et Pond.*, p. 202); but this is in a work of science and authority: and Oughtred (before the date of Bernard's book) says that it is "taken (or rather mistaken) that 60 statute miles make a degree." It is most likely that the sea league would in the first instance be taken from the common league; and certainly 15,000 feet, or 2.84 statute miles, is almost the same as the length which different deductions will give for the old land league.

We now proceed to the main question, the length of the old English mile: premising that the utmost we can attempt is a clear proof that the old popular mile differed considerably from the modern mile. The gradual changes of this old mile (which the general history of itinerary measures may lead us to suspect) must be traced out by closer investigation of antiquarian authorities than mathematicians have been wont to make, and better estimation of their relative values in a mathematical point of view than antiquaries have hitherto been capable of making.

There is a tradition among antiquaries (Sir H. Ellis, 'Preface to Domesday') that this old mile was somewhere about a statute mile and a-half. This tradition is not to be relied on; for though in all probability it agrees with the truth, yet it may have arisen from another circumstance. We have more than once heard it proved by the assertion that, even within the memory of man, distances were measured in the remote parts of the country by a longer than the

statute mile; for instance, that York was said to be 150 miles from London, while it is really more than 199 statute miles. This is perfectly true; but the reason is perhaps different from that given, as the following account will show:—

The first actual measurement of the roads in England, in statute miles, was made by John Ogilby, cosmographer to Charles II., and was published by him in 1675, under the title of 'Britannia,' with copious descriptions, and 100 copper-plates of the roads, in a large folio volume: the instrument used was called by him a *wheel-dimensurator*, by others, a *way-wiser*, and answers entirely to the perambulator now in use. Various editions of this work were published, of which we have seen three, and D'Anville mentions a fourth. It is worth noting that this measurement, as compared with older ones, soon came into general use: thus in a little work for men of business, called 'The Complete Tradesman, or Exact Dealer's Daily Companion,' London, 1684, we find a list of Ogilby's distances from town to town, compared with those formerly adopted. The latter were called by Ogilby *computed* miles, and the meaning of this word might be doubted, but it is proved to mean miles in common use by previous publications. Thus in Samuel Morland's 'Description and Use of Two Arithmetic Instruments,' &c., 1673 (or two years before Ogilby's publication), we find the distances called "computed" by Ogilby set down as the (supposed) real distances. D'Anville appears to have seen an edition of Ogilby (of which there is one at least) in which the word *computed* is always contracted into *com*. This he supposed to mean *common*, and the whole of his chapter on English itinerary measures ('Mésures Itinéraires,' cap. x.) must in consequence be read cautiously, as he assumes to be indisputable that there was a common mile in use at the Revolution, which was about a quarter longer than the statute mile. But on the authority of the silence of Bernard and Greaves above referred to, we must remain of a different opinion, and must suppose that the computed miles preserved by Ogilby had been intended to represent the number of statute miles, but erroneously given.

What then may these computed miles mean, which had served the common purpose in the estimation of distances? The word *computed* never meant reputed, but was always applied to a result of reckoning of some kind or other. Ogilby says, "Whence these computations arose is altogether uncertain; the nearest conjecture is, that they seem to exclude the whole length of the towns, and to be the distance from the end of one town to the beginning of the next, not regarding the fractional parts of a mile, but taking the lesser integer." The computed miles always give a smaller figure than the measured ones, or the same, never a greater; and a little examination will render it difficult to suppose that the preceding explanation can be the true one. For independently of its having been the known practice to measure the roads from a conspicuous part of every town, the preceding will not explain differences of four, five, and even seven miles in a stage of less than thirty; neither will it explain long stages being often of the same number of computed as of measured miles. Our own conviction is that the computed miles are nothing more than distances measured on a map in a straight line from town to town, which differ from those measured on the roads more or less, according to the deviations and curvatures of the roads. Should this opinion be correct, we might expect beforehand, first, that the roads in the neighbourhood of the metropolis would appear more direct than the general average; secondly, that the principal roads would show indications of being more straight than the average deduced from all classes, and from cross as well as direct roads. Both these things appear in the general results, and we can clear ourselves of the suspicion of bias in our selection of instances by throwing that task on others. In the first place the roads near London agree so much better in the computation, so called, and the measurement, that both Ogilby and D'Anville notice the circumstance, and conclude that a shorter mile was in use in the neighbourhood of the great city. We find on examination that such is the case with most of the twenty-mile distances about London, which yield about 120 measured miles for 100 computed miles; and this happens particularly with those routes which come earliest in Ogilby's work; but 120 would have been increased almost up to the general average by taking twenty miles on every road out of London.

Secondly, in the 'Exact Dealer's Daily Companion,' already quoted, there is a selection of the roads to which most importance was attached, upon the whole of which 3953 computed miles answer to 5020 measured miles, or 100 computed miles give 127 measured miles. According to D'Anville, Ogilby's whole work gives 7679½ measured miles of road, and 5765 computed, so that 100 computed miles make 133 measured miles. Hence the remaining 2659 measured miles give 1812 computed miles; or, off the principal roads, 100 computed miles give 147 measured miles. These results place, in such large numbers of miles, insuperable difficulties in the way of any explanation which should equally apply to the greater and lesser roads; and it seems to us that there remains only the hypothesis that the computed miles were map-measured distances, and that the larger and more important roads were straighter than the rest. If our hypothesis be correct, these computed miles should represent distances on an incorrect map, which in fact they do. We found them agree somewhat better with the county maps in old editions of Camden's 'Britannia' than with our modern maps. And long after this article was written,

* This of course refers to the measure of Snell, which gave 353,285 feet (A.D. 1616).

we found that our explanation not only had been given, but was at one time so common as to admit of reference as to a thing understood. Dr. Grew, in a paper in the 'Philosophical Transactions' (1711), speaking of some erroneous "under-reckoning" says, "their mistake seems to have been, their reckoning only by the maps; that is, by computed and not by measured miles."

It is believed that, since the time of Ogilby, the roads have been much shortened by the various acts of parliament. *Have the mile-stones been always altered accordingly?* or was the increased speed of stage-coaches, towards the end of their career, in part the result of calling a shorter line of road by the same number of miles? To try this question, we shall compare a few distances from place to place, as given in Ogilby's 'Britannia,' with those in Mogg's edition of Paterson's 'Roads' (1824), altered so as to start from the same point, namely, the old standard in Cornhill:—

	Ogilby.	Mogg.
London to Worcester	112	114
„ Berwick	339	337
„ Bristol	115	117
„ Bridgnorth	142	142

The measures in Ogilby may of course be erroneous; but as they were certainly made with a sufficient instrument, and exhibit every appearance of care, and as in our country it is nobody's business to see that all succeeding milestones are altered when a mile of road is saved in the middle of a line, we suspect strongly that a remeasurement would often show the distances of 1824 to be too long. And in truth the four distances just given are now said to be of 111, 337, 108, and 138 miles.

The credit of the antiquaries' tradition, which would otherwise be considerable, is destroyed by its probable origin, as above stated. We now come to another species of evidence, the testimony of foreign writers. The new measures of any country found their way abroad but slowly at the beginning of the 17th century, and we shall not therefore be surprised to find foreign writers of the middle and end of that century varying from then existing measures in their statements. We shall first take the geography of Varenus, first published in 1650, and edited in 1672 by no less a person than Newton, then Lucasian professor. The following sentence was allowed by the editor to pass without comment:—"Triplicia habent Angli milliaria: majora, quorum 27½ aquant gradum sive 19 Hollandica; mediocria quorum 50; minima quorum 60 vel 55." Now the mile of Varenus is described by himself as containing 18,000 Rhineland feet, each of which, according to Dr. Bernard, is 1·033 English feet. Whence it may be deduced that the three miles described as English by Varenus severally contain 2·43, 1·33, and 1·11 statute miles (taking "60 vel 55" to be 60). We have no doubt that Varenus has here got hold of the leuca, the old mile or half the leuca, and the modern statute mile, which, being not sixty years old when he wrote, was not, though the contemporary legal measure, more accurately known than the others. Again, Ozanam, in his 'Mathematical Dictionary,' 1691, makes the English mile a quarter longer than the Italian mile, that is, considerably above the statute mile; but his accounts of itinerary measures are so evidently theorised into round hundreds and thousands of geometrical paces, that no dependence can be placed on any specific results drawn from them. If his geometrical pace be five French feet (Pauca, p. 179), this English mile (which he states at 1250 paces) is 6250 French feet, or 2219 English yards, that is, 1·26 statute miles. But this is hardly worth notice, for no value of the geometrical pace can be taken which will make Ozanam's account of measures consistent with itself. We shall take one more conjectural determination of the mile, derived from the sea league of the 17th century. Gunter states this at three miles of 5000 feet in a mile, the league being the twentieth of a reputed degree. The author of the 'Exact Dealer's Daily Companion,' above cited, calls it three Italian miles, or 4904 yards. Now if the original league were the land measure, then the mile (or half of the leuca) would have been 2452 yards, or 1·4 statute miles.

D'Anville endeavours to make the old mile the same thing as the original French league, or the Roman mile and a half [LEAGUE], taking the *computed mile*, already discussed, as the old measure. But independently of the mile thus considered not being long enough (and we have no instance of an itinerary measure shortening by time), the distinction between the mile and the league seems to have been one of the most common notoriety from the time of the earliest manuscripts; and previous to this time the confusion which might have made D'Anville's supposition true had already lengthened the league by 500 paces.

The only way of detecting the length of any measure, a copy of which is not absolutely preserved, is by the knowledge of some quantity, which having been handed down in terms of the old measure, and being still in existence, can be re-estimated in terms of the new measures. Unfortunately we have no very exact measurements of well-known lengths; nevertheless by using such as we have, and taking the mean of a considerable number, the odds are much against any very serious error remaining in the result.

About 1478 William Botoner, commonly called William Wircestre, or William of Worcester, made a tour in various parts of England, and wrote, apparently for his own use, a large number of memoranda, which remained in the library of Corpus Christi College, Cambridge, and were published in 1778, by Dr. Nasmyth, with the title, * 'Itinera-

rium Willelmi de Worcestre.' The date of the writer is well settled, for he asserts that in the year 1473 he presented to the bishop of Winchester his own translation into *English* of Cicero de Senectute. This William of Worcester was given to measurement: he records the dimensions of the churches which he visited, and the numbers of miles between the several towns. From the latter enumerations we have collected the most definite instances, which we have compared with our latest road-books, as follows (W is the number of miles in W. of W.'s account; R in the road-books):—

	W.	R.
From Oxford to Farringdon	12	17½
„ Farringdon to Wotton Bassett	15	19
„ Gloucester to Tewkesbury	7	11
„ Shepton Mallet to Glastonbury	5	8½
„ Glastonbury to Bridgewater	9	15½
„ Bridgewater to Taunton	7	11½
„ Taunton to Wellington	5	7
„ Wellington to Collumpton	10	12½
„ Collumpton to Exeter	10	11½
„ Ottery St. Mary to Exeter	10	13
„ Plymouth to Saltash	3	4½
Totals	93	131½

To give the best chance of a correct result which our present means afford, we must increase this 131½ modern road miles in such proportion as will make them correctly represent the same roads at the time when William of Worcester travelled. This we have no data for doing, and any supposition we may make must rest on its own intrinsic probability. To neglect this correction altogether would make the preceding give 100 old miles equal to 141 statute miles, and this is the lowest conclusion which can be formed. But if five per cent. of deviation has been corrected since the old account, that is, if what is now 100 miles would have been 105, then 100 old miles may be stated at 148 statute miles. This conclusion, and even a stronger one, may be reinforced from a totally distinct quarter. But first let it be observed, that since roads have no tendency to lengthen, but the contrary, it may be inferred that such of the preceding instances as make the old mile least are most probably those in which the distances have been shortened; and instead of being the cases of most weight, are precisely the reverse.

Though the preceding instances are quite sufficient, yet it may be satisfactory to name one or two short distances in which a very large mistake is impossible. The following, were they the only ones, would lead us to suspect that the old mile was even longer than a mile and a half statute. William of Worcester says that Wokey Hole is about half a mile from Wells, whereas, by the Ordnance Map, it is a mile and six-tenths in a straight line from the centre of the town. Again, Merkysberry (now Masberry) Castle is placed by him at two miles from Wells on the opposite side: it is now three miles and three-quarters in a straight line from the centre of the town. Lastly, Fenny Castle is said to be a mile and a half westward towards the marsh, whereas what is now called Castle Hill is two miles and three-quarters westward. These instances are more convincing than the preceding as to the mere use of a longer mile, though not so well adapted for its determination.

We must now remove the question to Palestine. In the description of the earth given by Roger Bacon (Jebb, pp. 180-236) he generally follows Pliny, and gives distances in Roman miles, except only when treating of those parts which the Crusaders visited, and other Eastern countries. In this part of his account Bacon relies much on the conversation and writings of a certain Willielmus, who went on a mission from the king of France to the Tartars (Turks), in 1253, and on the oral accounts of other travellers. But the country on the distances of whose towns he is most precise in his information is Palestine itself. By taking fifteen well defined instances, and measuring the corresponding distances on Major Rennell's map in parts of inches, we have the following, the first column being the number of leucæ in Bacon, the second the number of inches in Rennell. (We omit sea-distances, as likely to err considerably.)

	B.	R.

Totals	152½	16·03

* With it was published the 'Itinerary of the Holy Land,' by Simon Simeon. With it was also published the tract on Leonine Verses referred to in the article on that subject.

The scale of Rennell's map is three inches to a degree of latitude; and the only remaining question is, how much must this 16.03 inches, which is a total of distances measured in the shortest lines from place to place, be increased to allow for the deviations of the roads? If we assume that the deviation was equal to that in England at the Revolution, we must * increase 16.03 in the proportion of 100 to 127, which gives 20.3581. It must be remembered that the more allowance is made for deviation, the longer is the leuca; and we think it is the least supposition which can be made, to suppose the deviation on routes in Palestine no greater than in England. Dr. Bernard states that it was the practice of the Oriental geographer Abu Rihan (Al Biruni or Birunius) to deduct one-fifth from distances measured on the roads, to obtain the true distances in a straight line. This amounts to increasing the number of miles measured on the map in the proportion of 100 to 125, and is practically accordant with the preceding rule in a question of which the data are as rough as in the present one. The testimony is valuable as referring to roads in the East, and at the period to which Bacon's account refers. The leuca is then, on these suppositions, .1335 of an inch on Rennell's map, or .0445 of a degree. The length of the degree in these latitudes being assumed at 363,500 feet, we deduce 3.064 statute miles as the length of a leuca, or 1.532 statute miles as the length of the old mile. If we were to reject the correction for deviation, the result would be 1.206 statute miles, which is unquestionably too small.

In 1422 Sir Gilbert de Lannoy was sent by Henry V. of England, on a tour of military observation in Egypt and Syria. His account is published (from a manuscript in the Bodleian) in the 21st volume of the 'Archæologia.' He never mentions the league more than once or twice, and gives all his distances in miles. From his account of Egypt we soon found that no hypothesis would make his distances agree with modern travellers. He places the city of Cairo, for instance, three miles from its port Boolak, which distance is now called only *one* mile. [KAHIRA, in GEOG. DIV.] But on examining his distances in Palestine there appears almost a certainty that he used a smaller mile, of which two and a half (and not two) make the league of Roger Bacon. The following are all the comparisons which his work affords us the means of making:—

	Bacon. Leagues.	Lannoy. Miles.	League in Miles.
From Joppa to Aco	24	60	2.5
„ Aco to Tyre	9	25	2.78
„ Tyre to Sidon	8	20	2.5
„ Sidon to Baruth	8½	25	2.94
„ Jerusalem to Joppa	12	30	2.5

But even Lannoy's mile must be longer than our statute mile; and it is difficult to explain the difference. One thing is certain, that Lannoy's mile in 1422 cannot be the same thing with that of William of Worcester in 1473, or that of Bacon in 1250, being shorter than either.

So far our conclusions proceed upon assumptions of the highest probability; and the result is, that from the English measurements we may infer that 100 ancient miles certainly exceed 141 statute miles, while from those in Palestine they are most likely not much less than 153 such miles. It is highly probable that the result is nearer to 153 than to 141. If we were to take a mean of both results, giving them equal weights, the mile thus obtained would be probably too small, and this result is 1.47; so that (as mentioned in LEAGUE) the ratio of 145 to 100 is the very least which is admissible, and perhaps too small even for a minimum. It seems to us that a more probable result would be obtained by taking 153 as a result of the measure in Palestine (for it is hard to believe that the correction for deviation could have been too much), and giving this number twice as much weight as 141 in forming a mean of the two. This gives 149 in place of 147; or, roughly speaking, we think it by no means improbable that 100 ancient miles were as much as 150 statute miles, and tolerably certain that they exceeded 145 such miles. At the same time there is evidence enough that very different miles were in use among writers, and also that the most ignorant confusion between ancient and modern measures frequently existed. Sir John Maundeville, for instance, says, "Afte the auctoures of astronomye, 700 furlonges of erthe answeren to a degree of the firmament: and tho ben 87 miles and 4 furlonges. Now be that here multiplyed by 360 sithes; and than thei ben 31,500 myles, every of 8 furlonges, afte myles of oure contree." The old astronomical authors use the stadium, which is here made to be the English furlong, a measure with which it had no connection.

There is certainly this difficulty in the way, that [LEAGUE] the ancient minimum distance between two market-towns must have been 19 modern statute miles, which seems a great distance. But it must be remembered that this appearance is a consequence of the notions derived from the modern interpretations of the courts, which make the leuca to be a statute mile; so that 7 miles has long been the legal distance. This interpretation is so preposterous that it must be thrown aside; for even if the mile of Bracton and Fleta were the mile of the books, and not the mile of the people, the leuca would be 10,000 feet,

* We take this from some rough trials, out of Ogilby's book, but we rely more on the eastern geographer presently mentioned.

or two statute miles all but the tenth of a mile. And the reason given by Bracton certainly requires some greater distance than seven miles. For he implies [LEAGUE] that the third of a day's work should be half the distance of two markets; and gives a time for buying and selling not longer in duration than that allowed for going to the market. Reading this paragraph by the modern interpretation of the courts, the time of business would be that in which a laden horse or market-cart would go three miles and a half; and if, taking into account the badness of roads in the 15th century, we allow even as much as two hours for this, then the day's work would be only six hours. According to our reading, the time of going nine miles and a half would be the time of business; or allowing three miles an hour, the day's work would be something more than nine hours. It may however be possible, and not improbable, that the mile of 5,000 feet, or that of the books, was that of the courts of judicature, which would give about 12½ statute miles as the distance in question.

We conjecture that the length of the ancient mile arose from that confusion between the mile and the leuca which is referred to by Ingulphus. [LEAGUE.] The leuca of fifteen hundred paces would, when the foot attained its permanent length, be 1.42 modern statute miles, to which the term mile being applied, we have the probable beginning of the old mile, that is, we adopt D'Anville's conclusion on different grounds. If in the meanwhile the leuca of 2000 paces came into use (as, according to Ingulphus, it did), which would be called in the books two miles (as in fact it was two miles of the writers), it is by no means surprising that a new leuca of two long miles should be formed from the mile of the people. This would be but a poor conjecture for the establishment of a measure; but it has great force in reference to a mile, the existence of which is separately proved. And though Ingulphus states that the word leuca was introduced as meaning a mile, yet it is more likely that the new measure should have been introduced under the old name, than the new name for the old measure: it is moreover tolerably certain that the conquerors would attempt to introduce both their measure and its name, while the people would be able to resist the latter, but not the former.

The origin of the statute mile may perhaps be explained as follows: The furlong, or quarantena, was not a part of the Roman itinerary system of measures. It grew out of the perch, or perticata, a measure originally of small lengths, as in buying or selling of land, 40 of which were made into one by the simple name of forty-long, or furlong. The great variations of the perch, in different parts of the country, induced the legislature, at a very early period, to fix it at five yards and a half. It did not harmonise with the book-system of measures, and we see [LEAGUE] that when it was introduced there, the mile was awkwardly described as seven furlongs and a half, three perches, and two palms. The legislators of Elizabeth, who were well acquainted with the stadium, seeing the mile of the books (and perhaps of the courts) making upwards of seven furlongs and a half, might very naturally restore the nominal accordance of the old and modern systems, and at the same time avoid fractional quantities, by lengthening the mile into eight furlongs.

MILITARY POSITIONS. [TACTICS.]

MILITARY PUNISHMENTS. We have little knowledge of the manner in which offences against military discipline were punished by the Greeks; but it appears that, for sedition or mutiny, the commander of an army had the power of causing the ringleaders to be seized and instantly put to death. Agamemnon, in the 'Iliad,' threatens such as may desert, that they shall die; and Alexander the Great, when a mutiny took place partly in consequence of the jealousy excited by the favour which he showed to the Persians, caused thirteen of his Macedonians to be executed without a trial. (Arrian, 'Anab.' vii. 8.) The military law of Athens prescribed the punishment of death for the crime of desertion while on service. Occasionally, however, this serious offence was only punished with imprisonment or fine; for, whatever might be the power of an Athenian commander over his soldiers in the field, it is probable that he would be very careful how he exercised it; since, at the termination of a campaign, a man who might consider himself unjustly treated could compel his officer to answer for his conduct before a tribunal of his countrymen. Among the Lacedæmonians, cowards and deserters were either put to death or publicly disgraced; offenders who did not suffer the extreme penalty were made, when at home, to wear a party-coloured dress, and were obliged to submit in silence to any insult which the meanest citizen might choose to offer. Disgrace also fell upon the soldier who, in action, had the misfortune to lose his shield.

The Romans punished crimes committed by the soldiery with great severity. For the gravest offences soldiers were beheaded or crucified; and under the Pagan emperors some, probably such as professed the Christian religion, were burnt alive or exposed to wild beasts. On the occurrence of a mutiny, every tenth, twentieth, or hundredth man was sometimes chosen by lot, but generally only the ringleaders were selected for punishment. Deserters and seditious persons were frequently, after being scourged, sold for slaves; and occasionally the offender was made to lose his right hand, or was bled nearly to death.

If a soldier absented himself from the spot assigned to him for the night-watch, or if he was found asleep at his post, he was the next day brought before the tribune, who on the fact being proved, sentenced

him to suffer the bastinado. It appears from Polybius (vi. Ex. 2) that the tribune having gently touched the offender with his staff as a signal, the persons appointed to inflict the chastisement fell upon him and struck him repeatedly with sticks or stones, frequently with such violence as to cause his death: the culprit was allowed to escape by flight if able; but in this case he was never permitted to return to his country, or, if he did return, no person dared to afford him shelter or relief.

Punishments of a like nature, but less severe, were inflicted upon a soldier who was guilty of theft, or of giving false testimony either in his own favour or against a comrade. For certain breaches of discipline the offender suffered a temporary deprivation of his pay, the forfeiture of his arms, or degradation from his rank. Sometimes he was sentenced to remain outside of the camp exposed to the chance of being taken by the enemy, or he was made to stand for a certain time in an unmilitary dress before the prætorium. In some cases a culprit was sentenced to perform hard labour, to exchange into a corps of inferior rank, or to be entirely dismissed from the service with disgrace. Punishment was also inflicted on a soldier for cowardice or for losing his arms. A centurion guilty of a breach of discipline was deprived of the staff (a vine branch) which he carried as an emblem of authority.

A dictator could sentence to death any offender against military regulations; and the consuls had the power of exercising summary jurisdiction in capital cases. Punishments were ordered by the legionary tribunes, and by the præfects of the allies, with the concurrence of a council.

Among the nations of modern Europe the punishments for military offences were, till lately, no less severe than they were among the Romans. Besides the infliction of a certain number of lashes with cords, soldiers convicted of theft, marauding, or any other breach of discipline which was not punishable with death, were sentenced to run the gauntlet as it was called. For the execution of this sentence the regiment was drawn up in a double line; and each man being furnished with a small stick, generally of osier (except the grenadiers, who used their belts instead of the sticks), the culprit, naked to the waist, was either marched slowly or allowed to run as fast as he could, according to circumstances, from the head to the rear extremity between the two lines, each man striking him as he passed along. In certain cases the offender was afterwards expelled from the regiment, and sometimes also from the town or district with a charge never to appear there again under pain of death. The punishment of the knout, in the Russian army, is inflicted with a leathern belt on the naked back of the offender.

Cavalry soldiers were formerly frequently punished by the *picket*, as it was called; this consisted in the man being made to hang by his hands from a beam during a certain time, a stake with its upper end made sharp being planted in the ground under him; so that, when from weariness he could no longer keep himself up, his foot was pierced by the stake: this kind of punishment has been long since abolished.

Confinement without light during a certain number of hours was, and still is, a frequent punishment for being absent without leave from parade, either on account of drunkenness or from any other cause. Formerly the pillory was a punishment awarded to offences of this nature.

Besides the punishments of death and transportation, which, for great crimes, are within the scope of military law, in the British army, breaches of discipline are visited by flagellation, temporary imprisonment, extra drills, extra guards, and the performance of fatigue duties; but punishments consisting of protracted periods of confinement to barracks accompanied with laborious employments, inflicted at the discretion of commanders of regiments, have been abolished for many years, not however before the most serious mortality in consequence had made it absolutely necessary.

While an army is in the field, breaches of discipline must be punished with promptitude and more than ordinary severity. It might be presumed that acts of treachery will seldom be committed; desertions to the enemy however do occasionally take place; but the more usual crime is that of quitting the ranks on a lawless expedition of plunder, which is generally accompanied with gross acts of outrage, violation of chastity, often murders, committed on the defenceless people of the country; and no doubt can exist that soldiers guilty of such crimes should be shot or hanged on the spot. Even when the crime is less heinous, the well-being and perhaps the safety of the army may be perilled in consequence of the resentment excited among the surrounding inhabitants; such disorders must therefore be repressed by making signal examples of the offenders. In the presence of an enemy there can scarcely be a more serious offence than intoxication; miscarriage of an enterprise, and defeat, with the loss of numbers of gallant men in an action, may be the fatal consequences of indulgence under such circumstances. Trial, and on conviction punishment, should be if possible immediate; the army may change its position or cantonments; delay takes place, and the necessary witnesses are at a distance, or in the mean time removed by the accidents of war. A long interval between the commission of a crime and its punishment diminishes the fear of the latter by opening to the culprit another chance of escape; it moreover diminishes the effect of the punishment

as a warning: the impression produced by the crime wears off, and the punishment assumes, in some measure, the appearance of an act of cruelty. Employment of the accused meanwhile in any of the duties of the camp or field is a condonation of his offence that makes his subsequent punishment inhuman, and unmilitary, if not quite illegal.

The circumstances of an army in peace, and in war, or rather when in the presence of an enemy, are very different: in the former case soldiers have no opportunity to commit treason or to pillage a country; and since the generality of the men who then enter the army are such as have a fair moral character, great crimes among them are as unfrequent as they are among an equal number of men in any other condition of life: the punishments for such offences as may then be committed may therefore with propriety be of the same nature and degree as those which would be adjudged for corresponding offences by the ordinary courts of justice. Imprisonment for a time, employment in laborious tasks, but particularly a forfeiture of pay and pension, where the offender is without a family depending on him for support, might, probably with advantage, be made the punishment for military offences.

Serious breaches of discipline are still punished with the lash; but the maximum number of lashes that may be inflicted is now these several years past reduced to fifty. But the objections to this description of punishment are of a kind not to be removed or modified by any modification in the degree of severity with which it is inflicted. It is both cruel and disgusting; it is permanently degrading, leaving on the character an indelible impression, and on the skin for life the marks of disgrace which, if discovered by any accident, cannot fail to produce a prejudice against the individual, how well soever he may have conducted himself subsequently to the infliction. It falls, moreover, with unequal effect on different persons according to the state of their health, or of their nervous systems at the time; and not unfrequently, according to the will of the person who administers or who superintends the punishment. It may be added that many of the soldiers who are drawn up to witness it, can neither avoid sympathising with the culprit nor becoming dissatisfied with a service in which they are exposed to such disgrace and suffering.

Happily the terrible scenes that used to be exhibited at the triangles in the British army have now ceased for ever. General Sir Charles Napier, in his 'Remarks on Military Law,' states that forty years before the time at which he wrote (1837), he frequently saw from 600 to 1000 lashes inflicted under sentence by merely regimental courts-martial; and in those days a man who had suffered a part of the punishment was often brought from an hospital when the wounds were barely healed, to receive the remainder. A milder code is happily substituted in these days for the preservation of military discipline. The practice of giving rewards for good behaviour, now so happily introduced in the military service, and the instruction obtained at the regimental schools, will in time, it is hoped, operate a beneficial change in the characters of such men as have not, from nature or from early education, a just sense of moral rectitude and of the obligations all are under of punctually and faithfully discharging the duties they owe to their country. The existing code is particularly described in the article *MUTINY ACT*, *post*. (See Sir C. Napier's *Remarks on Military Law*.)

MILITARY TENURES. [FEUDAL SYSTEM.]

MILITIA. The body of soldiers raised for the defence of a nation may be called the militia of that nation; but in Great Britain and Ireland the term is applied particularly to those men who are either chosen by ballot or volunteer to serve for a certain number of years within the limits of these realms. The regulations of the militia service differ widely from those of the conscription on the Continent; since under the latter the troops become members of the regular army, and may be marched beyond the frontiers of the state; whereas the militia is enrolled only for home service, and may be said to constitute a domestic guard. Nothing corresponding to modern militia can be said to have existed among the ancients. In the Grecian states every citizen was a soldier; and every person, between certain ages, in the city and in the provinces, was obliged to serve in the Roman armies wherever they might be employed.

The military force in this country in the time of the Saxons was formed by a species of militia, and every five hydes of land were charged with the equipment of a man for the service. The ceorles, or peasants, were enrolled in bodies and placed under the command of the Ealdermen or chiefs, who were elected by the people in the folk-motes.

After the Norman conquest of the country the proprietors of land were compelled, by providing men and arms in proportion to their estates, to contribute to the defence of the realm in the event of a threatened invasion. The troops were raised under the authority of *commissions of array*, which were issued by the crown; and the command was sometimes vested in the persons to whom the commissions were granted; though frequently the high constables, or the sheriffs of the counties, commanded in their own districts. This militia seems, at first to have been liable to be marched to any part of the kingdom at pleasure, but in the reign of Edward III. it was decreed by a statute that no man thus raised should be sent out of his county, except in times of public danger. From the reign of Philip and Mary

the lords-lieutenant have had the charge, under the sovereign, of raising the militia in their respective counties.

Charles I. having, by the 'Petition of Right,' been deprived of the power of maintaining a disposable body of troops in the country, found himself, in 1641, unable to suppress the rebellion then raging in Ireland; and was in consequence induced to commit the charge of restoring peace to the care of the parliament. The latter immediately availed itself of the circumstance to get into its own hands all the military force of the nation; and in the following year the two houses passed a bill in which it was decreed that the power over the militia, and also the command of all forts, castles, and garrisons, should be vested in certain commissioners in whom they could confide. The king having refused his assent to the bill, the parliament made a declaration that it was necessary to put the nation in a posture of defence, and immediately issued orders to muster the militia; on the other hand, the king issued commissions of array for a like purpose to some of the nobility, and thus commenced that war which desolated the country for several years.

When Charles II. ascended the throne, the national militia was re-established on its former footing, and the chief command was vested in the king. The lords-lieutenants of counties were immediately subordinate to the sovereign, and granted commissions (subject, however, to the king's approbation) to the field and regimental officers who commanded under them. New regulations respecting the amount of property which rendered persons liable to the charge of providing men and arms were then established; and at that time no one who had less than 200*l.* yearly income or less than 2400*l.* in goods or money could be compelled to furnish a foot soldier; nor could one who did not possess 500*l.* per annum, or an estate worth 6000*l.* be made to provide a man for the cavalry. Persons having less property were required, according to their means, to contribute towards finding a foot or a horse soldier. The militia was then mustered and trained, by regiments, once a year and during four days; but the men were mustered and trained, by companies, four times in the year, and during two days each time. At the periods of mustering, every man was obliged to provide himself with his own ammunition.

These regulations, being found to be expensive, at length ceased to be observed, and the trainings of the militia were discontinued in every part of the realm except the city of London. In 1756, under an apprehension that the country was about to be invaded by a French army, considerable bodies of Hanoverian and Hessian troops were brought over for its defence: the spirit of the nation revolted however at the disgrace of being indebted to foreign mercenaries for protection; and these troops being sent back to the Continent, a national militia was again raised and organised under the sanction of an act of parliament in the 30th year of George II. The measure was generally popular, though it did not meet with universal approbation; and there were many persons who maintained the opinion that, for want of military knowledge and habits, this species of force could not be relied on in the event of its being called into active service. Experience has however shown that such an opinion is quite destitute of foundation; and it was soon afterwards admitted that, when well disciplined, these constitutional battalions rivalled those of the regular troops in the performance of all military evolutions. It may be observed here, that the greater part of the 16,000 British troops who gained the battle of Talavera were men drafted from the militia regiments at home; and so recently had they joined the army in Spain, that in the action many of them bore on their accoutrements the numbers of their former corps. (Napier, vol. ii.)

The militia laws were repealed in the 2nd year of George III., when a new act regulating the service of this force was passed; and in the 26th George III. all the previously existing statutes relating to the force were formed into one law. New regulations however were made by acts passed in the 42nd, 49th, 51st, and 52nd years of the same reign, and these with the acts passed in the 15th, 16th, 17th, 18th, and 19th Vict., contain the law applicable to the militia at present. The militia of the kingdom is now placed under the lords-lieutenants of counties, appointed by the sovereign, who have power to call them out and train them annually, and is subject to the provisions of the mutiny act, or articles of war. The sovereign until lately was only empowered to employ it in any part of the United Kingdom, but not out of it. In 1813, an act was passed allowing the militia, when volunteering, to be formed into provisional regiments to co-operate with the regulars; and in 1855, by special act, her Majesty was enabled "to accept the services of the militia out of the United Kingdom for the vigorous prosecution of the war." The militia of Great Britain may serve in Ireland, and that of Ireland in Great Britain: the period of service for each, out of the island to which it belongs, being at most two years. When called into active service the officers rank with those of an equal grade in the regular army, but as the juniors of each grade, and they may receive promotion for meritorious services during a rebellion or an invasion; but no officer of militia can serve on a court-martial at the trial of an officer or soldier of the regular troops.

All persons not labouring under bodily infirmity and not specially excepted, are liable to be chosen for private militia men, by ballot, in each parish, and are compelled under a penalty of 10*l.* to serve either personally or by substitute. Volunteers paid, by consent of the inhabitants, by parish assessments, may however be substituted for

balloted men. The persons excepted are—peers of the realm; commissioned and non-commissioned officers and privates serving in the regular forces; half-pay officers of the navy, army, and marines, and commissioned officers who have served four years in the militia; members of corps of yeomanry and volunteers, and privates serving in the local militia; seamen and persons doing duty in the royal docks, at the gun-wharfs, and powder magazines; also persons employed under the direction of the Board of Ordnance; resident members of the two universities; clergymen of the Established church; also Protestant dissenting preachers, provided they take the oaths of allegiance and supremacy, and exercise no other occupation, or only that of school-master; constables or other peace-officers; articulated clerks; apprentices; free watermen on the Thames; poor men having more than three legitimate children, and persons above 45 years of age. To alleviate the distress of a poor man, when drawn for the militia, and who has provided a substitute, the churchwardens of the parish are bound to return to him a sum not exceeding 5*l.*, or half the current price of a substitute. No one having served personally, or by substitute, during three years in the militia, can be obliged to serve again till it comes to his turn by rotation; but if a man has served as a substitute for another, this does not exonerate him from serving again if chosen by the ballot.

The militia is trained and exercised by battalions or regiments twice in a year, and during fourteen days each time, or once in a year for twenty-eight days, at the discretion of the lords-lieutenants or their deputies.

The supplementary militia is an additional body of men which was first raised in 1793, for the defence of the country at that juncture. It is still continued to be raised when the necessities of the state require it, and it is subject to the same regulations as the ordinary militia. The local militia was a body raised in 1809, for the purpose of replacing, in certain districts, the corps of volunteers. By the 52nd George III., this force may be marched to any part of Great Britain in the event of a rebellion or an invasion, and it may be kept embodied till six months after the former is terminated or the latter repelled. Persons enrolled in the local militia cannot be compelled to serve in the regular militia till one year after their period of service in the former has expired.

The whole amount of the regular militia forces in Great Britain alone in 1806 exceeded 200,000 men, and with the local militia and volunteers the force which might have been assembled in arms amounted to more than twice that number, or nearly 500,000 men.

When the militia were called out during the late war with Russia, the numbers, according to a parliamentary return of the 14th March, 1855, were—in England, 44,198; Scotland, 4461; Ireland, 13,095: total, 61,754. These numbers fluctuated very much, owing to the numbers who volunteered into the line.

In France a militia was first raised from the provinces during the reign of Louis XIV.; but the several corps were disbanded after the peace of Ryswick. In 1726 was organised a force of the like kind, consisting of men chosen by lot from the towns and villages, and held in readiness to be assembled when required; and in 1778 these provincial troops were formed into 106 battalions. Since the Revolution of 1792, the National Guard may be said to constitute the militia of France.

In the United States of America, by an Act passed in 1792, the principal provisions of which are still in force, all able-bodied white male citizens between the ages of 18 and 45, with certain exceptions, are enrolled in the militia; and when drafts are to be made for active service, the individuals are selected by ballot, as in this country. The persons excepted are the executive, judicial, and representative officers of the union, those who are employed in the post-office department, &c.; and, in some of the states, persons are exempted who have scruples of conscience against bearing arms. The president has the power of calling out the militia of the states; and, when on active service, it is subject to the same rules and articles of war as the regular troops, but courts-martial for the trial of militia offenders are composed of militia officers only.

A national militia, when properly constituted, is an institution of the highest utility to a state, the men being engaged in military occupations only so long as may be necessary for becoming qualified to serve as soldiers when called upon to take the field, and being at all other times employed in labours subservient to the practice of the useful arts. They thus possess the united characters of defenders of their country and of contributors to its prosperity, while they remain connected in social union with their fellow-citizens, and are interested, like them, in the support of the laws and in the preservation of good government. It is in some respects otherwise with the soldiers of a regular army, devoted exclusively to the profession of arms, and, though their services are indispensable in the prosecution of foreign wars, have few feelings in common with the civil portion of the community; and who, except in a nation like Great Britain, where the military power is duly subordinated to the civil magistrate, might, under the influence of an ambitious chief, become dangerous to the liberty of their country. The system of embodying militia regiments for long periods, which has prevailed since the Crimean war, cannot be defended, except on the ground of urgent necessity, as they can then no longer be formed of the same class of men; while, from the constant volunteering into the line, the discipline is impaired.

				(only 3.7 according to Young.)	

From this analysis it would appear that milk is a compound fluid, chiefly consisting of oleaginous and albuminous materials, with different salts.

According to Dr. Prout, "albuminous and oleaginous principles may be considered already fitted for the purposes of the animal economy, without undergoing any essential change in their composition." And thus, by the action of the organs of the parent, the food is brought into a state very favourable for its assimilation in the body of the young, without taxing severely the digestive organs of the latter. The salts present in the milk serve also important uses, especially the phosphate of lime by consolidating the bones, which, at the time of birth, are soft and cartilaginous. The period when lactation in the human offspring should cease must vary with the vigour and progress of development of the infant; but in general nine months is the proper time for suckling, and its continuance beyond that period is injurious both to parent and child.

The milk of cows or other animals is extensively used as the food even of adults, and, though insufficient alone, is a most valuable ingredient of diet. It is often enjoined as the food of invalids, especially of persons who have a tendency to consumption.

Milk is also used as an antidote in cases of poisoning by some metallic salts, such as corrosive sublimate, perchloride of tin, sulphate of copper, &c.

Though cheese is in general difficult of digestion, fresh-pressed curd is often found to suit the stomach of persons affected with disease of that organ. (See Abercrombie, 'On Diseases of the Stomach.')

Milk may be brought to a dry state, and powdered, in which condition it keeps for a length of time; and by dissolving it in tepid water an artificial milk may be formed, capable of being used at sea, particularly for children during long voyages. [MILK, and FOOD, in NAT. HIST. DIV.]

Milk, in its commercial relations, has been affected in a remarkable degree by the opening of railways. Under the old system, London and other great towns had their entire supply of milk from dairies in and near the towns themselves. [DAIRY.] The adulteration, so much complained of, was due to the small dealers; the milk was sent from the large establishments in a pure state. Attempts were more than once made to insure the genuineness of the milk sold by retailers, by establishing joint-stock companies, and sending out the milk in locked cans; but the companies failed as commercial speculations. This system, though not superseded, is greatly lessened by the facilities of railway conveyance. Farmers and dairymen within fifty miles of London can send up milk at an average cost of about three farthings per gallon for freight, and sell it to the smaller dealers. New York and other cities of America, are supplied in a similar way.

Much useful progress has been made in so treating milk that it will keep good for a considerable length of time, and thus be available at times and places where cows cannot be kept. We will briefly describe some of the processes adopted. Moore's essence of milk is prepared by placing the milk in long shallow copper pans, heating it by steam to 110° Fahr., adding a little sugar, and stirring for four hours; the milk loses three-fourths of its bulk by evaporation; and the rest, as a very thick cream, is put into small tin cases, soldered down, steeped in boiling water for a time, and taken out to cool. This milk will keep good for a long period. Blatchford's solidified milk is thus prepared. About 112 lbs. of milk are mixed with 28 lbs. of white sugar, and a teaspoon-ful of bicarbonate of soda; the liquid mixture is exposed for three hours in an enamelled iron pan, to the heat of steam; while it is at the same time being constantly stirred, and a blast of cool air blown upon its surface. This is continued until the milk is converted into a kind of creamy powder, which is cooled, weighed into

ARTS AND SCI. DIV. VOL. V.

parcels of 1 lb. each, and pressed by heavy weights into brick-shaped pieces; these bricks are grated into powder when the milk is to be used. Grimwade's desiccated milk has a little sugar and alkali mixed with it; it is heated and stirred over a hot water boiler until as thick as dough; then dried into hard cakes, crushed beneath granite rollers, and bottled. This milk was used by Miss Florence Nightingale in the hospitals at Balaklava and Scutari. Fadeuille's desiccated milk is prepared nearly in the same way as Grimwade's; and a suit for infringement of patent was brought by one inventor against the other in 1859. At the Aberdeen Meeting of the British Association, in 1859, the Abbé Moigno gave a brief description of four kinds of milk preserved by methods adopted in France. Villeneuve's is rendered solid by the addition of solid substances; but it is no longer milk proper. Signac's is a kind of syrup of milk and sugar. Maber's is prepared by putting the milk into a vessel, excluding the air, exposing it to a steam atmosphere of 100° centigrade, and sealing it up in bottles; Moigno found this kind of milk perfectly good after five and a-half years keeping. The Abbé brought to Aberdeen some milk which had been prepared by De Pierre's process, the details of which were not fully made public. This milk, unlike others in a prepared state, is liquid. Heat is applied in some peculiar way, so as to remove a sort of diastase or animal ferment which exists in minute quantity in milk, and which is the real cause of its speedy decomposition. The milk brought by Moigno from France to Aberdeen had undergone a good deal of shaking during its travels; but it was pronounced by Professor Christison to be perfectly sweet and fresh.

There are other processes for preserving milk, mostly in a dry or a pasty state; but the above will sufficiently illustrate them all. Some of the preserved milks are over-sweetened with sugar, while others afford proof that the cheese-making stage has just been touched; and it is evident that the process requires to be conducted with great precision.

MILKY WAY. It is desirable, in describing astronomical objects, to keep as close as possible to the words of those who are accustomed to the sight and description of such things. Two passages in Sir John Herschel's 'Astronomy' will describe the Milky Way, and the theory of it, by Sir William Herschel, with excellent brevity and distinctness.

"There are not wanting *natural* districts in the heavens, which offer great peculiarities of character, and strike every observer: such is the Milky Way, that great luminous band which stretches, every evening, all across the sky, from horizon to horizon, and which, when traced with diligence, and mapped down, is found to form a zone, completely encircling the whole sphere, almost in a great circle, which is neither an *hour* circle nor coincident with any other of our astronomical *grammata*. It is divided in one part of its course, sending off a kind of branch, which unites again with the main body after remaining distinct for about 150°. This remarkable belt has maintained, from the earliest ages, the same relative situation among the stars; and when examined through powerful telescopes, is found (wonderful to relate!) to consist entirely of stars scattered by millions, like glittering dust on the black ground of the general heavens.

"If the comparison of the apparent magnitudes of the stars with their numbers leads to no general conclusion, it is otherwise when we view them in connection with their local distribution over the heavens. If indeed we confine ourselves to the three or four brightest classes, we shall find them distributed with tolerable impartiality over the sphere; but if we take in the whole amount visible to the naked eye, we shall perceive a great and rapid increase of number as we approach the borders of the Milky Way. And when we come to telescopic magnitudes," or stars of so small a magnitude as to be invisible except through a telescope, "we find them crowded, beyond imagination, along the extent of that circle, and of the branch which it sends off from it; so that in fact its whole light is composed of nothing but stars, whose average magnitude may be stated at about the tenth or eleventh.

"These phenomena agree with the supposition that the stars of our firmament, instead of being scattered in all directions indefinitely through space, form a stratum, of which the thickness is small, in comparison with its length and breadth; and in which the earth occupies a place somewhere about the middle of its thickness, and near the point where it subdivides into two principal laminæ, inclined at a small angle to each other. For it is certain that to an eye so situated, the apparent density of the stars, supposing them pretty equally scattered through the space they occupy, would be least in a direction of the visual ray (as s A) perpendicular to the lamina, and greatest in that of its breadth,

as s B, s C, s D; increasing rapidly in passing from one to the other direction, just as we see a slight haze in the atmosphere thickening into a decided fog-bank near the horizon, by the rapid increase of the mere length of the visual ray. Accordingly, such is the view of the

U U

construction of the starry firmament taken by Sir William Herschel, whose powerful telescopes have effected a complete analysis of this wonderful zone, and demonstrated the fact of its consisting entirely of stars. So crowded are they in some parts of it, that by counting the stars in a single field of his telescope, he was led to conclude that 50,000 had passed under his review in a zone two degrees in breadth, during a single hour's observation. The immense distance at which the remoter regions must be situated, will sufficiently account for the vast predominance of small magnitudes which are observed in it." [HERSCHEL, SIR WM., and HERSCHEL, SIR JOHN, in BIOG. DIV.; NEBULÆ; and STARS.] But to the above it must be added, that the fifty thousand stars thus mentioned as contained in a zone of 15° by 2° include only those which could be steadily seen and distinctly numbered; besides which, twice as many more were suspected, of which only occasional glimpses could be got for want of sufficient light.

The Milky Way may be described in general terms as extending three or four degrees on each side of a great circle inclined at an angle of about 60° to the ecliptic, which it cuts in the northern hemisphere between the horns of Taurus and the feet of Gemini, and in the southern hemisphere between Sagittarius and Scorpio. Beginning with the part nearest to the North Pole, it nearly covers Cassiopeia and Perseus, and then, becoming thinner, passes through Auriga, between Taurus and Gemini, and near the back of Canis Major through Argo. It then narrows considerably, and passing under the hind feet of Centaurus, widens again near Ara. A little above the last constellation, and before it again meets the ecliptic, it divides into the two streams above mentioned, which contain between them a long thin strip passing through part of Scorpio, Serpens, Aquila, Vulpecula, and Cygnus. In Cygnus the streams reunite, but immediately separate again, finally reuniting higher up in the same constellation, from whence the main stream reaches Cassiopeia, &c.

Sir John Herschel, in his 'Results of Astronomical Observations made during the years 1834-5-6-7-8, at the Cape of Good Hope,' 4to., 1847, has some valuable remarks on the general appearance and telescopic constitution of the Milky Way in the southern hemisphere; and has also given an accurate delineation of that portion of it which extends from the constellation Antinoo through Centaurus to Monoceros.

The Milky Way was called by the Greeks *γαλαξίας*, (whence our word *Galaxy*), or *κύκλος γαλακτικός*, and by the Romans *Orbis lacteus*. The mythology of the former people on the subject is as edifying as usual: Hyginus fixes on Eratosthenes the most common story, namely, that the Galaxy arose from the milk of Juno, who pushed Hercules away from her breast (where he had been placed by Jupiter) on learning that he was the son of Maia. Nor does the above accurate writer forget to mention that others held the appearance to have arisen from young master Hercules having been a greedy child, and having filled his mouth too full. Others thought that the whole was not milk, but ears of corn which Isis dropped in her flight from Typhon. Another fable, mentioned by Plato, makes the Milky Way to be a broad causeway through the heavens for gods and heroes to walk upon; another, that it is the part of the heaven which was singed when the horses of the sun ran away with Phaeton. These stories are a proper prelude to the speculations of the philosophers which followed. Some of the Pythagoreans are reported to have supposed the Milky Way to be an old and disused path of the sun, out of which, some said, he was frightened by the banquet of Thyestes; others, a reflection from the sun. Anaxagoras is said to have thought it was the shadow of the earth: Aristotle supposed it to be sublunary, and to consist of exhalations, of the same matter as comets. Posidonius took it for a band of fire; Theophrastus for a solid and luminous band, joining together the two hemispheres; while Diodorus thought it was celestial fire shining through the clefts of the solid heavens. Democritus hit the true explanation, namely, that it is a congeries of little stars too small to be separately seen—an opinion which both Plutarch ('De Placit. Philos.,' l. iii., c. 1) and Manilius mention. Shortly after the invention of the telescope, Galileo announced that he had resolved the whole of the Milky Way into stars. "Est enim *Galaxia* nihil aliud quam *innumerarum stellarum coacervatim consitarum congeries*: in quacunque enim regionem illius perspicillum dirigas, statim stellarum ingens frequentia sese in conspectum profert quarum complures satis magnæ et valde conspicuæ videntur, sed exiguarum multitudo prorsus inexplorabilis est." ('Nuncius Sideris.') It is however not easy to suppose that Galileo's resolution of the Milky Way was complete; and we may here see how necessary is attention to minute description. When Sir J. Herschel, in the paragraph cited above, states the stars to appear "like glittering dust on the black ground of the general heavens," we know that, if the observer can be depended upon, he has completely resolved the continuous light in question: but if he only says, with Galileo, that he detected innumerable stars, we are only sure that he has distinguished the nearer stars, and may suppose that the more distant ones still formed a Milky Way behind them. That this must have been the case with Galileo (whose telescopes would never distinctly show Saturn's ring) may be confidently asserted. It must also be remembered that Galileo had completely resolved several nebulae, and might easily have completed his assertion as to the Milky Way from analogy. Kepler ('Dioptr. Pref.') describes this resolution in a way which will be some guide as to its character: "Nebulosa stella

ostendit, ut in Via Lactea, duas, tres, vel quatuor clarissimas stellas in arctissimo spatio collocatas;" that is, two, three, or four stars were seen in the smallest space: this may very well correspond to Sir W. Herschel's estimate of 50,000 in the zone above mentioned, without the necessity of supposing that those stars were seen, which the forty-foot reflector would only show by glimpses. Sir W. Herschel counted seventy-nine stars, on the average, in a field of fifteen minutes in diameter, showing about as much of the heavens as is covered by one-fourth part of the moon. If, which may be suspected, the "arctissimum spatium" of Kepler meant the field of his telescope, the resolution thus obtained would not quite justify the conclusion, except as a probable deduction; the real and necessary inference would only have been, that stars invisible to the naked eye exist in every part of the Milky Way in considerable numbers.

MILL, MILLWORK. [COUPLING; GEARING; ROLLERS; SHAFTS; WHEELS; WINDMILL; WIND-SAILS.]

MILLENNIUM, a Latin word meaning a period of a thousand years, is applied by ecclesiastical writers to the period during which it is predicted in Scripture that the Church will be in a state of extraordinary prosperity, and which is to be preceded by the overthrow of her enemies, accompanied at its commencement by the first resurrection, or the resurrection of the saints, and followed by the destruction of Gog and Magog, and the general judgment. (Rev. xx.)

Respecting the state of the Church during the Millennium two opinions are held, both of which can be traced up nearly to the earliest ages of Christianity. The one is that Christ will reign in person upon the earth at Jerusalem, that the saints will reign with him and enjoy corporeal pleasures, and that the Jews will be restored to Palestine and exalted to the first rank among the nations of the world. This doctrine was held by Irenæus and others of the earlier fathers, not merely as their own opinion, but as the faith of the Church received from the Apostles. These tenets were also held by Irenæus in the 3rd century, and by Lactantius in the 4th, who expected the Millennium to commence very soon after the time at which he lived. On the other hand it was held by Origen, Jerome, and other fathers, who warmly opposed the doctrines just mentioned, that the passages of scripture on which they are founded must be taken in an allegorical sense, and that the Millennium will only be distinguished by the universal diffusion of pure Christianity in the world, and a consequent decrease of physical and moral evil: though Nepos, an Egyptian bishop, wrote a book against the allegorists, as he contemptuously styled the adversaries of the Millennium. The opinions of Origen, however, have been adopted as the belief of the orthodox Church, and have been almost universally received in modern times. The followers of the late Rev. Edward Irving, and some other small sects, as well as many individuals among other bodies of Christians, still hold the doctrine of the personal reign of Christ on earth. Such persons are commonly called Millenniumists, the name applied in the early ages of the Church, together with the corresponding Greek word Chiliasm, to those who held these opinions. (Lardner's 'Credibility'; Mosheim, 'Eccl. Hist.,' cent. iii. and iv.)

MILLET. The stalk of all the species of millet resembles a jointed reed, having at every joint a long broad leaf, which embraces the stalk with its base. It is an annual plant, growing quickly, yielding an abundance of small grains, which are set round a compact spike at the top of the stalk. The stalk itself is filled with a saccharine juice.

Millet thrives best in a light sandy soil, and if sufficient space is allowed between the plants to weed and hoe them during their early growth, they will afterwards overtop and smother all weeds, and yield an abundant return with little labour and without much manure. The seeds, however, require a climate warmer and drier than that of England to ripen properly. Millet is cultivated largely in the southern parts of Europe.

In the East, millet is used as food for men; but in Europe, though it is sometimes made into loaves and cakes, and frequently into puddings, it is mostly used for feeding poultry and domestic animals. The leaves and panicles are given, both green and dried, as fodder to cattle.

Millet has been described by botanists under the generic terms *Holcus* and *Sorghum*. The most general species, the common Indian millet, known in Nubia by the name of *Durra*, is described under *SORGHUM*, in NAT. HIST. DIV.

Sorghum saccharatum has latterly been introduced for the large quantity of sweet fodder which, when it is ripe, its straw and leaf afford for stock.

MILLION. [MENSURATION.]

MIME (from the Greek *mimos* (μῖμος), an imitator), a dramatic performance of irregular form among the Greeks, in which occurrences of real life were clothed in a poetical dress. It usually consisted of a single scene, mostly comic, sometimes with such dialogue added as the excitement of the moment prompted. Mimes appear to have been common entertainments at feasts. Sometimes they were acted on the stage. Sophron of Syracuse (born about B.C. 420), who wrote in the vulgar dialect of the Doric Greek of Sicily, is considered the inventor of this species of composition. His mimes were in rhythmical prose, and were highly esteemed by Plato, who is said to have carried to Athens the taste for this species of composition. With the exception of a few fragments, and the names of some of his mimi, the works of Sophron are lost. The fragments of Sophron are collected in the 'Museum

Criticum,' No. VII. His son Xenarchus, who lived under Dionysius during the Rhegian war, B.C. 393, also wrote mimes. We have specimens of a mime in the fifteenth idyll of Theocritus. Philistion of Nicæa, another writer of mimes, was contemporary with the latter years of Socrates. Suidas (*Φιλιστιαν*) calls his mimes *biologic*, or "pictures of life."

Among the Romans, mimes seem to have been nothing but irregular harlequinades, probably the lineal ancestors of our "Punch." In the time of Augustus, Bathyllus and Pylades divided the taste of the Roman capital as actors of mimi. Among the mimographers of Rome we find Mattius, Laberius, and Publius the Syrian, the second of whom died B.C. 43, when the third was in the height of his popularity. Laberius acted as well as composed mimes. The Roman mimes were written in verse, but were often delivered extempore, and the manners represented had much local truth. The actors in such pieces had also the names of *mimes*, distinguishing them from the pantomimists, who confined their representations entirely to action. In the reigns of the earlier emperors we meet with other mimographers of celebrity, but none came up to the reputation of Laberius and Publius.

(Ziegler, *De Mimis Romanorum*, Göttingen, 1789, quoted in 'Conversations Lexikon:' Schlegel, *Dramatische Vorlesungen*, lecture viii.)

MIMOTANNIC ACID, *Cachoutannic Acid* ($C_{30}H_{18}O_{16}$). The tannic acid produced from catechu possesses some properties different from that of the tannic acid from oak bark, and Berzelius proposed to call the one mimotannic acid, from *Mimosa*, and the other quercitannic acid, from *Quercus*, the name of the oak.

MINARET (from the Arabic *menarah*, a lantern), in Saracenic and Eastern architecture, a very slender and lofty turret, having one or more projecting balconies around it, which divide it externally into two or more stories. They are used in Mohammedan countries for the purpose of calling the people to prayers, and therefore serve the purpose of belfries. They are, however, generally more numerous than such purpose actually demands, there being one at each angle of the building, and sometimes a greater number, and hence they become highly characteristic features, as well on account of their frequency as their tall, graceful, column-like shape, which causes them to contrast so picturesquely with the cupolas that crown the edifice, and together with which they serve to produce a pleasing and varied architectural outline. The resemblance to the column form is frequently greatly increased by the uppermost gallery being corbelled and ornamented for a short distance downwards, so as to assume the shape and mass of a capital, above which the structure is usually made to terminate in a small polygonal alcove, with open arches on its sides, and crowned by an ogive or bulbous dome. Many of the Turkish minarets are alike elegant in general form, and in their ornamentation. In some of those in India (as in the mosque at Ahmedabad) the carving is almost profuse in its splendour, but the outline is much less happy than the Saracenic examples.

MINERAL ALKALI. [SODIUM; SODA.]

MINERAL CHAMELEON. [MANGANESE.]

MINERAL PURPLE. [COLOURING MATTERS.]

MINERAL WATERS. Mineral waters, though generally characterised by possessing some principle different from what is found in common water, or some of the ordinary principles in unusual proportion, yet among these are reckoned certain springs which have no claim to repute beyond what is due to their extreme purity, such as Malvern and Holywell; or to having a higher temperature throughout the year, than the mean of the latitude where they are situated. These last are classed among the *thermal* springs, which are properly divided into two sections, the *mineralised hot* springs and the *unmineralised*, among which are some only tepid, such as Matlock, where some springs are 66°, the lowest of the class in Britain, and others cold, presenting this peculiarity, that the tepid springs rise from fifteen to thirty yards above the level of the river Derwent, whilst those which rise either above or below this range are cold.

For practical purposes mineral-waters may be classed under four heads, each susceptible of secondary heads, according as they are hot or cold, or have other peculiarities, namely: saline, alkaline, chalybeate, and sulphureous. It will not be possible to mention more than a few of the most important of each.

Saline aperient springs: of these some are hot, others cold. The chief are Carlsbad, Marienbad, Eger or Franzensbad, Kissingen, Wiesbaden, Baden-Baden, Seidlitz, and Salschutz, with Pullna, in Germany; Cheltenham, Leamington, and Harrogate in England; Dunblane, Pitcaithly, and others in Scotland.

Alkaline waters, owing their properties to different saline principles, are found at Carlsbad, Marienbad, Kissingen, Pullna, Salschutz, Ems, Töplitz, and Wiesbaden, in Germany; Vichy and Mont d'Or, in France; Harrogate, Scarborough, and other Yorkshire springs, Cheltenham, Leamington, Bath, and elsewhere, in England.

Chalybeate waters: with these acidulous waters are often reckoned, as the iron is often associated with much free carbonic acid gas. Some of the chief are Spa, Pyrmont, Schwalbach, Marienbad, Aix-la-Chapelle, and Seltzer in Germany; Tonbridge, Harrogate, and Brighton in England, and Peterhead, in Scotland.

Sulphureous waters: Aix-la-Chapelle, in Rhine Prussia, Bareges, and other Pyrenean springs, are hot; Harrogate, Askern, and others in Yorkshire, cold; Moffat and Strathpeffer in Scotland, also cold.

Ioduretted and other waters. Many springs have of late been found to contain a notable quantity of iodine or bromine, others contain both: Creuznach, in Germany, contains both, but most iodine; Llandrindod and Bualt in Radnorshire, the springs issuing from the lias at Leamington, Gloucester, Tewkesbury, and Cheltenham, contain iodine; bromine, but not iodine, exists in small quantity, in the saline aperient waters near London, such as Epsom, also in the springs from the coal-formation of Ashby-de-la-Zouch, Newcastle-on-Tyne, and Kingswood, and Bonnington near Edinburgh: Woodhall, near Ashby-de-la-Zouch, contains most iodine of any British springs yet investigated.

Organic matters, termed *Baregine*, *glairine*, *zoogene*, &c., have been found in many springs. Of these an account may be found in Dr. Lankester's 'Askern and its Mineral Springs,' p. 103.

It is impossible to give directions here for the selection of one kind of mineral water in preference to another. A decision on this point can only be made by a competent medical attendant. It may be permitted to say a few words on calcareous springs, by which is meant those waters in which some of the salts of lime predominate. These are generally hard. While flowing under ground the lime is often in the state of a soluble bicarbonate, but on reaching the external atmosphere, one portion of the carbonic acid escapes, and some of the carbonate of lime is precipitated. Hence these waters exert a petrifying effect on substances thrown into the springs or receiving wells. This is also the reason why such waters are best used on the spots whence they emerge, and ill bear transportation. Such waters should never be received in leaden cisterns or transmitted through leaden pipes. The chief mineral waters in England which belong to this group are Bath, Bristol, and Buxton. They are noted for their beneficial effects in those diseases which are connected with the presence or generation of an unhealthy acid in the stomach, such as gout, rheumatism, and some cutaneous diseases, in which the power of the water taken internally is often assisted by the use of the same water externally as baths. The change of mode of life generally adopted at watering places, the relaxation from hurtful over-exertion of mind and body, conduce to promote the health of the visitors to these places of resort.

MINERVA. [ATHENE.]

MINES. Mines are properly openings in the ground from which any thing is dug. Until an opening is made, the name is not properly applied, though the term is now generally used to signify coal, lead, iron, and so forth, before an opening is made for digging them out.

Mines belong to the tenant in fee-simple of the land, with the exception of gold and silver mines, which belong to the king by his prerogative, but by 1 W. & M. c. 30, a mine of copper or tin is not to be considered a royal mine, though silver be extracted from the ore. The owner of land in fee-simple is the owner of everything which lies in a perpendicular direction under the surface to any depth. A tenant for life, unless his estate is without impeachment of waste, cannot dig earth, lime, clay, or stone, except for the repair of buildings or the manuring of the land. In fact, the general principle is, that the land, which term comprehends everything in it or that is permanently attached to it, cannot be taken away by any other person than the tenant in fee-simple or a tenant in tail. Accordingly a tenant for life cannot open a new mine, but he may work mines which are already open, and he may open new shafts for working veins of coals which have been already worked. A tenant in tail has an estate of inheritance, and incident to it the power of committing waste, as by cutting down timber or opening mines.

If a man who has an estate in fee leases the land with the mines upon it, the lessee is thereby empowered to dig for the minerals; and if he leases lands on which mines are already open, the lessee may work them.

The freehold of all copyhold lands is vested in the lord, and it is a legal consequence that he has the freehold of the mines. In some cases a copyholder of inheritance has by the custom of the manor a right to the timber, and the lord has no right to dig mines, unless there be a custom which gives him the right.

If a man works mines under his own land, and follows the ore or other substance under his neighbour's land, he is a trespasser.

The act 7 & 8 Geo. IV. c. 30, § 6, 7, enacts certain punishments for malicious injuries done to mines. [MALICIOUS INJURIES.]

MINES, MILITARY, are excavations made in the rampart of a fortress, or underground, in order to contain gunpowder, which, being exploded, the rampart may be breached, or any works of the enemy, above or near the mine, may be destroyed.

The term *offensive* is applied to the mines which are formed by the besiegers of a fortified place; those which are formed by the garrison are called *defensive mines*, or counter-mines, this term having been given to the mines executed by the besieged, as they were the latest introduced in warfare. The cavity in which the powder is deposited is called the *chamber*; and the excavated approach to the latter is called the *gallery*, if the dimensions are above 3 feet by 4 feet; if smaller than this, a *branch*. These are termed ascending or descending, according to their direction, though if they are vertical they are termed *shafts*.

Two kinds of mines were anciently employed in the attack of fortresses. One of them was merely a subterranean passage carried under the walls from the exterior ground; and being suddenly opened

within the town, the assailants were enabled to enter the latter by surprise. The other kind was executed in a similar manner, and was intended to lay the rampart of the place in ruins; for this purpose, the gallery, having been driven as far as the walls, was carried on to the right and left under the latter, which were supported by props of timber till the time appointed for the assault was come; then, the props being drawn away or consumed by fire, a portion of the rampart fell into the ditch; and the troops, who were kept in readiness, passed over the ruins into the town. Mines of this kind are described in a relation of the siege of the castle of Boves near Amiens, at which siege Philip Augustus attended in person. At the siege of Melun, which was carried on by Henry V., king of England, and the Duke of Burgundy, in the year 1420, the besiegers having driven their mine almost up to the walls, and the besieged having executed a mine in opposition, a barrier was erected where the two galleries met, and there the king and duke fought with lances against two Dauphinois.

As the parties engaged two abreast, it is evident that the galleries must have been a considerable breadth. The old French writers occasionally applied the term mines to what were also then, and are now, called trenches. Thus, at the siege of Harfleur, in 1449, mention is made of broad and deep trenches by which the approach to the wall is said to have been rendered secure; and the same works are immediately afterwards called mines.

Gunpowder was, in 1487, used in military mining by the Genoese at the siege of Serezanella, a town belonging to the Florentines; but on this occasion without success. It is stated, however, in the life of Gonsalvo de Cordova, that Peter of Navarre, a Spanish engineer, formed mines with gunpowder at the siege of Cephalonia, near the end of the 15th century, when the Venetians and Spaniards took the island from the Turks. And in 1503 the same engineer, or, according to Vallière, an Italian called Francis George, succeeded in taking by such a mine the Castle del' Ovo at Naples. This fortress was situated on a rock nearly surrounded by the sea, and had during three years resisted the united arms of the Spaniards and Neapolitans. From that time the practice of forming mines with gunpowder was almost constantly followed in the attack, and after a short time gradually in the defence of fortresses. So powerful was the effect of mines in the attack, that it was not an unusual occurrence for the besiegers after forming their mine to invite the besieged to see it, in order to bring about a surrender without further bloodshed. The besieged from very early times had a gallery placed a short way in advance of the foot of the wall, termed an *envelope* gallery, to warn them of the operations of the besiegers. From this gallery branches were run out, and used to what was termed "give the *camouflet* to the enemy's miners;" that is, a small charge was exploded, which, though insufficient to produce any surface effect, destroyed the besieger's gallery and suffocated his miners. From this to the adoption of ordinary mines was a small step. By means of 1173 mines, great and small, the Venetians defended Candia during more than two years (1666 to 1669) against the whole power of the Turks. By mines also, in 1762, the town of Schweidnitz was defended during 63 days by the Austrians against the Prussians. In the course of this last siege two of the mines fired by the besiegers had charges of powder amounting to 5000 lbs. each; and the depth of the charge below the surface of the ground was from 18 to 20 feet.

In the siege of any place the mining operations of the besiegers are directed to the discovery and destruction of the galleries of countermines; to the blowing up of any advanced works belonging to the garrison; to the demolition of the wall of the counterscarp, in order that the descent into the ditches may be facilitated; and, occasionally, to the formation of breaches in the principal ramparts. On the other hand, the countermines are employed by the defenders to destroy the trenches and batteries of the besiegers beyond the foot of and upon the glacis, the galleries made by the besiegers, and also the lodgments which may be made on the breaches or within the works. It is easy to perceive, therefore, that a system of countermines must add greatly to the strength of a place, by obliging the besieger to proceed with circumspection in his approaches above ground, in order to avoid the risk of being blown up at every step; and, according to Bousmard ('*Essai général de Fortification*'), if the glacis of a fortress be countermined, the duration of the siege, which otherwise would have extended to one month only, may be prolonged to six weeks.

By means of mines in the attack of a fortress, the besieger has a sure and certain method of gradually, it may be slowly or it may be rapidly, according to the ground, appliances, and activity of the enemy, but still a certain and irresistible means of reaching and destroying the defences of the besieged. And this with the loss of comparatively few men. The successful explosion of a mine by the enemy may destroy a few miners, while an assault costs hundreds or thousands of men. But yet almost every exploded mine is a step in advance for the besieger. Being superior in the field he seizes the crater formed by the explosion, incorporates it in his works, and pushes on from it by fresh galleries. The galleries of both besieger and besieged have been destroyed in the neighbourhood of the crater by the explosion of the mine, whether these were exploded by besieger or besieged. The besieged then pushing on again from his nearest undestroyed gallery, meets the besieger half way, unless, as occasionally happens by skill he circumvents him, but this half way has been a clear loss to the besieged and gain to the besieger. Hence no system of countermines

can render a work impregnable; but as a means of delaying the fall of a work, in fact of restoring as far as science can the equilibrium of attack and defence, it exceeds all the other means at the disposal of the besieged: it to a great extent renders the possession of superior numbers, position and material, on the part of the besieger, nugatory. The onward and irresistible advance of the besieger, rapid above ground, from the nature of the work is, though certain, slow in these underground operations. And he cannot neglect them. If the besieged have countermines the besieger cannot refuse to meet him with the same weapons. As the French engineers Gumpertz and Le Brun say, with respect to this, "The loss of a great number of men, and the discouragement of the whole besieging force, perhaps even their defection, would inevitably follow such a resolution. When, therefore, the front of attack is countermined, the besieger must call the miners of his army to his aid."

The great difference between civil and military mining is this. In civil mining the operations generally carried on at a great depth are in solid rock, whereas in military mining they are near the surface in soft ground, which requires supporting to prevent its falling in and crushing or stifling the miner. The principal portion of the art of the military miner consists thus in the management of these supports or linings. In permanent systems of countermines, that is, in fortresses furnished with defensive mines as a portion of their defence, the galleries, being made to last for years, are lined with masonry. Many different systems or plans for the arrangement of countermines have been suggested by the different engineers who have written on the subject. These, though varying much in many details having the same object in view, are to a great extent similar. They are disposed over the exposed portions of the front of fortification, and where an enemy would be likely to form his trenches, lodgments, and breaching batteries, that is, round the ravelins under the glacis, and in front of the bastions in the main ditch and also in the rampart. The object to be kept in view is to expose as little as possible of the galleries to the destructive effect of the enemy's mines; hence they should never, if possible, present their sides to the enemy, as the effect of a mine would be not only to destroy the gallery in its neighbourhood, but perhaps to cut off a large portion of uninjured gallery and render it useless for further defence. The galleries must therefore be disposed so as to present their ends to and lie in the direction of the enemy's approach. At the same time they should not be so far apart that the enemy might pass between them without being heard. As the sound of a pickaxe cannot be heard beyond 60 feet underground, from 100 to 120 feet is the greatest distance they should be asunder. And on the other hand they should be close enough for the mines fired in them to cover the intermediate space with their destructive effects without injuring one another. Assuming then that the galleries are 15 feet underground, which is considered the best depth for defensive purposes, they should for reasons which will appear from the action of the explosion explained further on, be at central intervals of 48 feet.

Space does not permit of our entering further on this subject: the reader is therefore referred to the article 'Mining, Military,' in the 'Royal Engineer Aide Memoire.' It may be stated, however, that the main gallery which, passing along the counterscarp, serves as the base of the system of mines, is termed the *magistral* gallery; the advanced galleries are termed *listening* galleries. If there be an intermediate gallery, parallel to the magistral, it is called the *envelope*; and those giving access from one to the other, *galleries of communication*.

In offensive mining, the earth is supported by wood-work. There are two different systems of mining, one with what are termed mining frames and sheeting, the other with cases. Mining frames for shafts consist of four pieces, two $4\frac{1}{2}$ feet long, and two 3 feet long, about $4\frac{1}{2}$ inches by 3 inches thick. The long pieces are made with tenons, which fit into mortices cut in the short pieces, which are further notched to one-third of their thickness; these being fitted together form the frames, which are placed horizontally in the shaft at intervals of 4 feet, and retain the sheeting planks, (which are outside them and prevent the earth falling in,) in their places.

Gallery frames differ from shaft frames in being composed of only three pieces, two uprights called stanchions, and a top piece called the capsill.

The system of mining with cases is more expeditious than with frames and sheeting; they have long been known as Dutch cases, and were introduced into the British service by General Sir Charles Pasley. They consist of four pieces about 1 foot wide, namely, two stanchions, a capsill, and a groundsill; and for ordinary work are cut out of 2 inch deal. The stanchions have tenons, 2" long by 3" wide, which fit into mortices of corresponding dimensions cut in the end of the capsill and groundsill. These form rectangular cases, which are placed touching one another if the soil is light, no sheeting being employed.

The dimensions of the different galleries and branches employed in mining are in the clear—

	Height.	Width.
1. Great Gallery	6 6	7 0
2. Principal Gallery	6 6	3 9
3. Common Gallery	4 6	3 0
4. Great Branch	3 6	2 6
5. Small Branch	2 6	2 0

1. Used for the descent of ditches and passage of cannon.
2. Used for the passage of troops, two deep.
3. Ordinarily employed for general purposes of attack, giving the miner room to work easily either on both or one knee, and is the most rapidly executed.

4 & 5. Employed for short distances, about 10 or 12 feet only, for placing charges, &c., as being more easily tamped.

When cases are used, mines can be driven at nearly twice the rate that they can with frames and sheeting: namely, great galleries and shafts about 1 foot an hour, common galleries about $1\frac{1}{2}$ feet an hour.

Ventilation requires to be well looked after in mines, for not only do the gases generated by the explosions of powder collect in the descending and ascending portions of galleries and often stifle the miner, but even under ordinary circumstances the air is so vitiated by respiration that a branch cannot safely be driven more than 60 feet. Hence openings should be made to the surface of the ground, and, if possible, concealed from the enemy, and communications made from adjacent galleries to create a draught. It also often becomes necessary to use artificial means of forcing air down into a mine, by means of a blower or bellows and metal pipes carried to the end of the mine.

The chamber in which the powder is placed is a cubical excavation formed on one side of the gallery, very little larger than is necessary to enable it to receive the box which contains the powder. When this is deposited, the vertical face of the chamber is covered with boards, which are kept in their places by short timbers fixed in horizontal positions between them and the opposite side of the gallery. The latter is then filled up with earth, well rammed, to an extent in the length of the gallery greater than that of what is called the *line of least resistance*; that is, a line imagined to be drawn from the chamber perpendicularly to the nearest surface where the crater would be formed. The mass of earth thus filling the gallery is called the *tamping* of the mine. A train of powder in a canvas hose, forming a tube about three-quarters of an inch in diameter, and for security contained in a wooden trough called an *auget*, or a *casing-tube*, is laid from the box in the chamber through the tamping to the place where the fire is to be applied; to its extremity is attached a piece of port-fire, which, being lighted, the fire communicates by means of the hose with the powder in the chamber, and an explosion takes place. Mines are also fired by means of what is called Bickford's fuse, which consists of powder encased in a kind of rope made of spun yarn, tarred. This fuse is waterproof, and not so liable to be accidentally ignited, and is especially adapted for damp ground. Electricity is also now constantly employed in firing mines. It was used by the Russians in their mines at Sebastopol, and by the English in the demolition of the docks, &c.

The dimensions of the crater or funnel formed by the explosion depend on the amount of the charge; its form may be considered as an irregular frustum of a cone, or paraboloid, and the mine is denominated *one-lined*, *two-lined*, &c., according as the diameter of the crater at the surface of the ground is equal to once, twice, &c., the length of the line of least resistance. Every explosion of this kind necessarily produces a compression of the earth in all directions about the chamber to a certain extent; and the mines formed with high charges have been denominated *globes of compression* from this circumstance. A line drawn from the chamber to the circumference of the crater, on the ground, is considered as the radius of the globe of compression.

The last mentioned description of mine was first employed by Belidor for the purpose of destroying the galleries of the besieger at distances far greater than had before been considered practicable. When a very small, or at least, comparatively to its depth, a very small mine is exploded, no crater is produced, but it is evident that the earth about must be compressed, and galleries, &c., destroyed to a certain distance: the radius of this sphere of compression is termed the radius of rupture. When a crater is produced, the solid compressed will no longer be a spheroid, but an ellipsoid, or nearly so, with its major axis passing through the centre of the charge, at right angles to the line of least resistance. With overcharged mines this radius of rupture is greatly increased: in fact it is found that with the ordinary or two-lined crater the radius of rupture, or semi-major axis of the ellipsoid, is 1.7 times the line of least resistance; and the semi-minor axis, or extent of compression downwards, is 1.3 times the line of least resistance. With a globe of compression producing a six-lined crater or maximum charged mine, these lines are 4.36 and 1.4 times the line of least resistance. It will be seen that the lateral effect increases much more than the downward effect, as might be imagined. This great lateral effect was employed by Belidor for destroying the galleries of the besieger: such mines are, from the circumstances of the respective cases, perhaps more applicable by the besieger than the besieged.

The rules for determining the charges of mines are founded on the results of experiment, and it is evident that the charges must vary both with the nature of the soil and with the proposed figure of the mine, that is, with the ratio between the diameter of the crater and the length of the line of least resistance. When a mine of the kind called two-lined is formed in common earth, the amount of the charge in pounds is considered as very nearly equal to one-tenth of the cube of the line of least resistance in feet; but for a three-lined and a four-lined mine it is supposed that the cube of this line should be multiplied by .21

and by .45 respectively. It is said that Belidor, somewhere about the years 1758 to 1762, fired three charges of 3600 lbs., at a depth of 12 feet, all of which produced craters of 36 feet radius, or six-lined craters. In an experiment made at Potsdam, when a four-lined mine was formed in a sandy soil by the Prussian Major Le Febvre, the cube of the line of least resistance in feet was very nearly equal to the charge in pounds. According to the latest experiments of the French engineers, the charges of powder necessary to remove one cubic yard (English) of material are as follows:—

Common earth		1.21 pounds (English)
Strong sand		1.64 "
Potters' clay		1.75 "
Loose sand		1.85 "
Old masonry		1.94 "
Freestone		2.14 "

Now the figure of the crater being supposed to be a paraboloid, of which the centre of the chamber is the focus—if a be the length of the line of least resistance in yards, and na represent the radius of the crater at the surface of the ground, also if $\pi = 3.1416$, we shall have

$$\frac{a^3 n^2 \pi}{4} (1 + \sqrt{n^2 + 1})$$

for the volume of the crater in cubic yards; therefore, multiplying this volume by the numbers in the above table, we should have the charge in pounds, which will hold good for mines up to three-lined craters.

The following rules, given by General Sir Charles Pasley, are very valuable, as deduced from experiment. L.L.R. meaning line of least resistance.

CHARGES AND EFFECTS PRODUCED IN MIXED EARTH.

To find the quantity of powder.	Multiply by	Gives powder in lbs. to produce No. lined crater.	Earth thrown out in depth.	Earth affected in depth.	Remarks.
L.L.R. ³	$\frac{1}{30}$	1-lined	Not defined	..	These experiments were in soil weighing from 90 to 122 lbs. the foot cube, and on a L.L.R. of 6 feet.
"	$\frac{1}{20}$	1½-lined	"	..	If more than 3-lined craters are not attempted the charges are pretty certain; above this they are not so certain; it is therefore better to use a number of small charges to produce a certain effect than one large one, the latter being very wasteful of gunpowder.
"	$\frac{1}{10}$	2-lined	"	..	In earth, try to produce 3-lined craters at 2-lined intervals, and never with a L.L.R. less than 6 feet.
"	$\frac{1}{4}$	3-lined	"	..	Earth and stones were with a 5-lined crater thrown 180 yards, with a 6-lined 270 yards, and with a 7½-lined 600 yards.
"	"	4-lined	L.L.R.	1½ L.L.R.	
"	2½	5-lined	1¼ L.L.R.	2 L.L.R.	
"	4	6-lined	1½ L.L.R.	2 L.L.R.	
"	8½	7-lined	..	..	
"	9¼	7½-lined	1⅝ L.L.R.	2½ L.L.R.	

In order to determine the proper size of the chamber, or rather of the box, which is to contain the powder, it will be necessary to observe that one pound of gunpowder occupies, in volume, about 30 cubic inches.

Experience has shown that the greater the charge of powder, the greater is the quantity of earth removed by the explosion. But this fact has its limits; for when the charge is considerable, since the whole of the powder does not take fire instantaneously, it will happen that the earth is partially displaced before the inflammation is complete so that fissures being formed in the ground, the force of the powder is spent in the air without producing any effect. Hence it may be concluded that there is a certain charge of powder which will produce a maximum of effect; and it is supposed by Belidor that, in earth of mean tenacity, the greatest craters will have their diameters, at the surface of the ground, equal to about six times the length of the line of least resistance.

MINIATURE. The term miniature would apply with equal propriety to every kind of painting executed on a minute or diminutive scale; but as commonly employed it includes only two, though somewhat widely different, kinds of painting. One of these is that style of ornamental painting, or illuminating, which is seen in its greatest perfection on the vellum pages of mediæval bibles, psalters, service-books, and other costly manuscripts: the other kind is that of small portraits executed chiefly on ivory, to which indeed the term has in its popular acceptance been of late years almost exclusively confined.

We will notice first the former kind of miniatures. The practice of enriching manuscripts with small paintings is very ancient. Many of the Egyptian papyri exhibit in their coloured hieroglyphics what are in their way admirable examples of miniature painting. These are painted in very vivid colours, and often display much artistic skill in their execution. From the marvellous skill and patience shown by the Greeks in the engraving of small figures on gems, we may conclude that they could paint with equal skill on a small scale, but we do not know that they practised this kind of painting to any extent. Among the Romans, books were occasionally adorned with small paintings in a very costly style for noble and wealthy persons. Pliny ('Hist. Nat.' xxxv. 2.) relates that Marcus Varro's work entitled 'Hebdomades' consisted of brief biographies of 700 illustrious men, from Homer downwards, each being accompanied by a portrait. There has been considerable discussion as to the manner in which these portraits were executed, some, and Müller amongst them, supposing that they were produced by a reproductive process—a sort of engraving and printing in fact—which enabled them to be repeated in each copy of the work. It is more probable that they were drawings or paintings though perhaps not of a very elaborate description. Seneca, Martial, and other writers refer to the practice of adorning manuscripts with painted illustrations.

In the decline of art the practice was preserved by the artists of Byzantium. Some writers believe that in the existing Byzantine miniatures we have in fact the connecting link between ancient and modern painting. But there is nothing in the character of these works to support the suggestion that the artists had inherited the traditions of the painters of ancient Greece. The earliest works were uncouth in drawing and barbarous in design, and owe both in general style and colour something to oriental taste. Yet they are of exceeding value as indicative of the character of the earliest dawnings of the revival of art under Christian influence. And as long as the practice continued of adorning manuscripts with these works they retain their value as documents in the history of art—representing on the whole faithfully its condition at the various periods, and in its earlier stages being almost the only examples of painting that have come down to us. These illuminations are also of great value, apart from their worth as works of art, as illustrating the costume, weapons, and even the architecture of their time.

The oldest existing manuscripts with miniatures are Byzantine, and of the latter part of the 4th, or beginning of the 5th century. During the first centuries, pictorial representations were studiously discouraged by the bishops of the church; but this was changed in the 4th century, and thenceforward we find the practice of illuminating manuscripts to have generally prevailed—the painters, being for the most part, monks, and a scriptorium, or establishment for writing and illuminating manuscripts, being attached to almost every wealthy monastery. The earliest extant illuminated Byzantine manuscripts are a book of Genesis in the Imperial Library at Vienna; one similar in subject and character, but fuller of miniatures, which formed one of the treasures of the Cottonian collection, but was unhappily almost destroyed by the fire at Ashburnham House; and a Virgil in the Vatican. The Vienna manuscript has the text chiefly in gold and silver, and is adorned with 88 miniatures; the Vatican Virgil contains 50 miniatures, the text being written in capital letters and in black ink. The Vatican Virgil was engraved by P. S. Bartoli (1677), at the expense of Cardinal C. Massimi, but the engraver corrected both the drawing and chiaroscuro, in accordance with the taste of his day, and the engravings are consequently valueless for any historical or critical purpose. More accurate outlines of them are given by D'Agincourt, 'Hist. de l'Art par les Monumens,' *Peint. tab.* 20-25. In the same work are given outline tracings of the miniatures of the best known manuscripts, which will enable the student to follow the fluctuating progress of the art in the hands of the Byzantine miniatori, to its greatest excellence about the 10th century, and thence trace its decline to the 13th century, and its temporary revival and termination, as far as Greece is concerned, in the 14th. Outline illustrations are also given in the same work of the miniatures of Italy, France, &c. A good notion of the style of colour of the different schools of mediæval miniatori will be obtained from the drawings by Mr. Owen Jones in the splendid work of Mr. H. N. Humphreys, 'The Illuminated Books of the Middle Ages' (fol., 1849).

The manner of the Byzantine miniatori was naturally imitated by those of the Italian monasteries, who followed very closely the types of their predecessors in their representations of the Saviour, the Virgin, and the Saints. As late as the 13th century the miniatori of Italy were mere feeble imitators; but by the beginning of the 15th century, they had assumed a higher place than their Greek masters, and works were produced in the Italian monasteries which in their way have never been surpassed for devotional feeling, elevation of sentiment, and the combination of a certain mystical grace and tenderness with ascetic severity. In their technical qualities these Italian miniatures are also of high excellence. The drawing, though still stiff, is pure and noble; the colour brilliant, yet harmonious, and the pencilling singularly light and neat. Vasari has given a particular account of several painters who distinguished themselves in this line of art, which though still chiefly practised in the monasteries, was, in the 15th and 16th centuries, no longer exclusively so. Oderigi da Gubbio, Giotto, Giral-

amo dai Libri, Giulio Clovio, Fra Angelico da Fiesole, Attavante, and several other painters, were also celebrated for their miniatures. Not only were illuminated manuscripts prepared for religious establishments, but the best artists found ample employment in the illumination of both secular and religious manuscripts for the chiefs of the princely houses of Italy. As the painting of larger pictures improved, however, miniatures became less in request, and in Italy as elsewhere, the production of illuminated manuscripts rapidly declined after the invention of printing.

The earliest school of miniature painters in the west of Europe appears to have been that founded at Finian in Ireland, in the first half of the 6th century, by St. Columba, who somewhat later founded a still more celebrated monastery at Iona, which was transferred a few years after to Lindisfarne. Several illuminated manuscripts, the work of Irish miniatori, are in the library of Trinity College, Dublin; one at least of them, a book of the Gospels, known as 'the Book of Kells,' being regarded as contemporaneous with Columba, if not the work of his hands. These Irish manuscripts are most remarkable for their borders, and other ornamental work, which are drawn with surprising delicacy and freedom, and are full of a playful and ingenious fancy; while the drawing of the human figure is ungainly and disproportioned, and the colour crude and conventional. It seems to be agreed that the other schools of the west of Europe derived their first impulse more or less immediately from that of Ireland. The art flourished in England during the Anglo-Saxon period, and the peculiarities of the Irish style of ornamentation are in it unmistakeably evident. The perfection to which the art had arrived at this time in England, is shown in the splendid manuscript of the Latin Gospels, known as the 'Durham Book,' executed between 698 and 720, and which is now in the British Museum; and in the no less famous Benedictinal of St. Ethelwold, now the property of the Duke of Devonshire. It was an Anglo-Saxon monk, Alcuin, who, at the invitation of Charlemagne, established the earliest schools for missal painting in the Frankish empire, the most important being those of St. Martin, at Tours, and Aix-la-Chapelle. Several of the early productions of these schools are extant, and show manifest traces of their origin. One of these, the Bible found in the tomb of Charlemagne, and now in the monastery of San Calisto, at Rome, is one of the most magnificent works of the kind in existence. Later, the art was prosecuted with eminent success in France, and a thoroughly national style was developed which attained its greatest perfection in the latter part of the 13th century.

In Germany and the Low Countries, the art took root somewhat later; but it ultimately attained a high degree of excellence. The museums of Germany and Brussels are rich in illuminated manuscripts of native production. By many, Memmling, the Flemish painter, is regarded as the greatest master of miniature painting, not excepting those of Italy. In England the art was a good deal modified after the Norman conquest by the prevalence of the French taste introduced by foreign monks; but the national spirit resumed its predominancy, and the English illuminations of the 13th and 14th centuries will bear comparison with the best contemporary productions of any other country. One of the finest remaining English manuscripts is the Willoughby, or Queen Mary's Psalter, painted early in the 14th century—a work full of life and spirit, admirable alike in design, drawing, colour, and execution. The art appears to have been practised in England down to the reign of Henry VII.

In the miniature painting of different ages and countries, there is of course, great diversity, not merely of style, but of modes of execution. Generally, however, it may be said, that the miniatures were painted on the vellum or paper with colours very finely levigated, and rendered opaque by being, for the shadows as well as the lights, mixed with white—the usual vehicle being gum, glue, or white of egg. D'Agincourt notices some miniatures, the colours of which are insoluble in water, and Dr. Dibdin speaks of others which seem to have been mixed with oil; but this is probably a mistake. In some manuscripts the artists appear to have covered their finished miniatures with a transparent wash of glue or varnish, which has materially assisted in their preservation. The colours used were not only selected and prepared with great care, but of the brightest hues, and applied and combined with much skill. Gold is freely used, gold back-grounds being frequent at most periods.

Notwithstanding the large number which must have perished from accident or neglect, or have been wilfully destroyed, the number of richly illuminated manuscripts still existing is surprisingly great. Most public, and many private collections contain numerous examples, and copies are eagerly purchased at very high prices whenever offered for sale. The Vatican, the Imperial Libraries of Vienna and Paris, and the British Museum are especially rich in examples of the various schools and periods; the monasteries of Italy, and the libraries of Oxford, Cambridge, and Trinity College, Dublin, also possess numerous and important, though less various collections.

We have now to speak of what are popularly known as *Miniatures*—the small portraits executed on ivory, either for decorative purposes, or to place in cabinets, lockets, or brooches. Miniatures painted in enamel are noticed under ENAMELS.

Although of later date than the works of which we have been speaking, portrait miniatures are by no means of recent introduction. Portraits were among the embellishments introduced by the mediæval

miniatori in the manuscripts executed by them for noble patrons; and after the decline of the practice of illuminating books, the production of portrait miniatures for placing in locket, frames, or cabinets, seems to have quickly grown into fashion. Ivory was early adopted as a more suitable ground than vellum for independent works, and its adoption led to a change in the technical processes. In mediæval miniatures, body colours—or colours rendered opaque by the admixture of white—were alone employed, and the ground or vellum was entirely concealed, the brilliancy of effect being obtained by the colours themselves. In modern portrait miniatures, the painters have very generally employed transparent colours, at least for the flesh tints; finding that the peculiar texture and semi-transparency of the ivory by showing through the tints of transparent colours caused them to “bear out,” as it is termed, with great brilliancy, besides imparting an exquisite softness, and much of that “inner light” which is so pleasing in carnations.

The ivory for miniatures is cut in very thin sheets, so as to retain as much as possible of its semi-diaphanous character, and when mounted, is “backed” by some perfectly white material. The painting is executed in water-colours, but by a process differing entirely from that known as water-colour painting. Ivory having a smooth and non-absorbent surface, the colour cannot be floated on in washes, or flat tints, laid one over another. The flesh tints and other parts requiring great delicacy of finish, are therefore entirely dotted, stippled, or hatched upon the surface. In the draperies and back-grounds, the colours are however often washed in with flat tints, the inequalities of tint or surface being afterwards got rid of, and the whole worked up by careful stippling. A mezzotinto scraper, and sometimes an engraver’s point or needle, is used for removing lights, securing due graduation of tints, &c. Gum is the only vehicle used with the colours besides water. Formerly, it was usual to execute the drapery and background of miniatures in body-colours, but the value of the ivory surface is thus lost, and the brilliancy lessened; while the general balance and harmony are almost always injured by the combination of opaque with transparent colours. The use of opaque colours has therefore been almost entirely abandoned by the best English miniature painters; though retained by French artists, who, it must be confessed, have employed them with great tact and skill.

Until of late years miniatures were almost invariably confined to the face and bust of a figure. They now often comprise the entire person, with all the accessories common to a “whole-length” portrait on canvas, and are painted on a sheet of ivory of a size which almost removes them from the class of miniatures. The process is, however, the same in these as in the bust portrait, where the adoption of a larger scale does not call for a somewhat larger handling. Sheets of ivory of sufficient size for these large miniatures—as we must call them for want of a more appropriate term—cannot, of course, be cut from the diameter of an elephant’s tusk, as are those for miniatures of the ordinary size. They are, in fact, thin veneers sawn from the circumference of the tooth, as described under IVORY, steamed and flattened under hydraulic pressure, and fastened with a composition of india-rubber to a mahogany panel. Some of these large paintings on ivory, as executed by Mr. Thorburn and others, have a broad and masterly effect; but they are after all hardly to be regarded as miniatures, and certainly do not possess the special characteristics of works of that class.

From the nature of the process miniature-painting requires great refinement of taste, dexterity and delicacy of hand, and patience in the artist. It recommends itself by the extreme softness, delicacy, and brilliancy of colour, and the portability and durability of its productions; and it has been pursued with great diligence and success in most countries, but especially in England, France and Italy. From the first the art has been successfully prosecuted in England. It appears to have been introduced by foreigners; but from the time of Nicholas Hilliard, limner to Queen Elizabeth and her successor, who learned the art from Holbein, England has always possessed miniature painters at least on a level with the best of their contemporaries. Among the immediate successors of Hilliard were Isaac and Peter Oliver, from the former of whom, in some respects still unrivalled as a miniature painter, we have portraits of several of the most illustrious of the remarkable men of his time. To them succeeded Alexander Hoskins and Samuel Cooper, and the latter, scarce inferior even to Isaac Oliver, has preserved the best likenesses of several of the most famous of the Commonwealth men, including Oliver Cromwell and John Milton. We need not continue the list: it will be enough to say that, whilst English miniature painters have always occupied a foremost place in their branch of art, it has been admitted even by foreign critics, that the English miniatures of the last and present generation unquestionably take precedence of those of the Continent. But whilst the artists have secured so honourable a position, the art itself appears doomed to give way before the advance of photography, as the miniature-painting of the mediævalists did before printing. Some of the best of our living miniature-painters have wholly or in part abandoned the practice of this branch of painting, and others of an inferior order are devoting themselves to painting “photographic miniatures,” or miniatures of which the basis is a feebly developed photographic positive. It is however to be hoped that fashion may show sufficient encouragement to the true miniature painter to preserve from decay this delightful branch of art. The practice of painting photographic miniatures

can hardly fail to develop a mechanical mode of painting which can scarcely rank as a fine art, however advantageous the study of photographic portraits may be, as an aid, to the miniature painter.

We cannot refer to a collection of portrait miniatures in either of our national museums; but several private collections have been formed in emulation, and partly from the debris, of the famous Strawberry Hill collection of Horace Walpole. Among the most celebrated are those of the Dukes of Portland, Buccleuch, Hamilton, Marlborough, and Northumberland, which embrace a large number of specimens from the Tudor period downwards. A choice selection from these and other collections was brought together at the Manchester Art Treasures’ Exhibition of 1857; and another, but comparatively private exhibition, was made partly from the same collections by the Archæological Institute, London, in the summer of 1860.

MINIM, in Music, a character, or note, formed of a round open head, and a stem descending or ascending from its right side—

When first introduced, the minim was the shortest note in music as its name (from *minimus*, the least) indicates. It is half as long in duration as the semibreve, and double that of the crotchet. [CROTCHET.]

MINIMS, or MINIMI, also called Pauliners, an order of religious whose asceticism exceeded even that of the Franciscans, of whom they were considered a branch. They were instituted about the year 1436, by Saint Francis de Paula, under the name of Hermits of Saint Francis, and confirmed in 1474 by Sixtus IV. Alexander II. changed the name of the order to that of *Minims*, as marking the humility of their order. In France they had the name of *Bons-hommes*; and in Spain that of the *Fathers of Victory*, in consequence of Ferdinand IV. gaining a victory over the Moors, according to a prediction of Saint Francis de Paula. In Spain a convent of nuns of this order was founded as early as 1495, followed in the course of time by other similar establishments. In France there was no female convent of this order till 1621: when one was established at Abbeville, and another subsequently at Soissons. No house of this order was ever established in England.

MINING. The art of mining embraces the contrivance and management of the operations necessary to effect the various objects requisite in a mine, as the discovery of mineral deposits, the preliminary trials of the value, and the final extraction of their produce by means of suitable excavations and the application of the requisite machinery. These occupations may be said to constitute the business of the miner in the more comprehensive signification of the term, and it will be evident that they demand an extensive range of acquirements in which knowledge, both practical and scientific, must be blended.

History of Mining.—A regular or detailed history of mining, however interesting in itself, would far exceed the limits of this article; we shall therefore briefly glance over some of the most important steps by which mankind have been led to their present bold and extensive operations for the extraction of metals and other mineral substances. The use of the metals, and consequently some process for their extraction and separation, may be traced to the most remote antiquity, and is there lost in the obscurity which veils the early history of our species. Moses ascribes the first use and manufacture of the metals to Tubal-Cain, the seventh in descent from Adam, who is said to have been the “instructor of every artificer in brass and iron.” Upon so brief a notice we are not entitled to build much, but it proves nevertheless that the use of the metals is almost coeval with the human race. Profane history likewise shows that it was known to the earliest nations of antiquity, as to the Assyrians, the Greeks, and Egyptians. Gold and silver were abundant among the ancients; an alloy of copper and tin formed the armour and weapons of the Greeks, although iron was not unknown among them, and of this metal the Roman weapons were formed. These facts do not, however, imply any great knowledge of mining, properly so called, as it is well known that metaliferous deposits are often found near the surface, frequently in a state of extreme purity, as gold and copper for example; and in early ages, when they had been so much less ransacked by the miner, these superficial deposits must have been much more abundant than at present, and probably furnished a large proportion of the metallic produce of those times. Most of the mines of antiquity were probably of a similar nature to the stream-works of Cornwall, and it appears from Strabo* (175, Casaub.) that the Phœnicians at that early time used to trade to Cornwall for tin and lead. In early times the demand for the metals could not have been very great; their use was then either as instruments of luxury or war, and thus confined to a limited class, so the quantity found near the surface was in all probability fully adequate, leaving but little inducement for deeper and more laborious research.

There is, however, evidence enough to show that operations similar to those of modern mining were carried on by the nations of antiquity. Herodotus (vi. 46, 47) observes that a mountain in the island of Thasos was completely burrowed by the Phœnicians in their search

* Strabo speaks of the Cassiterides, which can be no other place than Cornwall or the Scilly Islands; probably the former.

for the precious metals; and the curious fragment of Agatharchides preserved in Diodorus (b. iii. ch. 12, 13) shows that the art of forming shafts and passages for exploring mines and procuring the metals was well known in Egypt. The silver mines of Laurium in Attica were worked by the Athenians, to some extent at least, as early as the beginning of the 4th century B.C. Under the Romans the quicksilver mines of Almaden in Spain, and the lead and iron mines of Sardinia [MERCURY, in NAT. HIST. DIV.], were extensively worked.

It is singular to observe that an art for which this country possesses such great natural facilities, and which was certainly cultivated here both before the Roman conquest and during the Roman occupation of this island, should afterwards have fallen into decay, and indeed for a time have been chiefly practised by foreigners. Prior to the Norman conquest our mines had been much neglected, probably in consequence of incessant civil commotion; and subsequently to this period they were chiefly worked by Jews. In the reign of Elizabeth the art of mining had fallen into so much decay that an importation of foreign skill was found necessary to revive it; and the Germans, long and justly celebrated as skilful miners, received every encouragement to settle in this country and turn their attention to them. From this measure some success appears to have resulted, and in the following reign we find Sir Hugh Middleton, a citizen of London, deeply concerned in the lead and silver mines of Cardiganshire, from which he derived a large revenue, which was expended in that noble work from which the metropolis still benefits—the formation of the New River. About this time a new and important auxiliary was furnished to the art of mining by the application of gunpowder for blasting, which appears to have been first practised in Hungary or Germany; and an invention which had revolutionised the art of war thus became the means of effecting an equally extensive change in one of the most prominent arts of peace.

In the early part of the 18th century another important event took place in the history of English mining. The rich deposits of copper which have long constituted the principal mineral wealth of Cornwall, had up to this time been neglected, partly perhaps from this ore being confounded with “mundic,” or worthless iron pyrites, common in most mines, and partly from its lying deeper in the veins than the ores of tin, which had always formed the chief object of search. When at length the nature and value of the Cornish copper ore was fully recognised, a powerful stimulus was given to this new branch of mining, which has been carried on to the present time with great and increasing activity, the copper-mines of that county being now the deepest, the most extensive, and most productive in the world.

The great invention of the steam-engine, the progress of which during the last century exercised such vast influence upon our arts and manufactures, was early rendered applicable to mining in this country, and in a great degree contributed to the present perfect state of the art. Savery, who, if we except the somewhat equivocal claims of the Marquis of Worcester to that honour, was the first person who constructed a practically useful engine worked by steam, sought in the first instance the patronage of persons interested in mines, as we see by his publication entitled the ‘Miner’s Friend,’ in which he describes the nature of his invention and its applicability to draining mines. At this period our mines, although comparatively shallow, were much inconvenienced by water, especially those which were not in situations where hydraulic machines could be employed, and hence the application to them of this new power was at once obvious. The introduction of Savery’s engine into our mining districts probably led to the great improvements effected by Newcomen, a resident in Devonshire, which vastly extended its utility, and indeed completely altered its principle. Their conjoined patent was taken out in 1705, and from that date the steam (or rather, atmospheric) engine became a most useful auxiliary in the hands of the miner, and was very generally employed for draining mines, not only in Cornwall, but in the coal-mines of Staffordshire and the north of England. The great improvements introduced by Watt in 1765 and succeeding years were quickly appreciated by the mining interest, and his engines were speedily introduced into the mining districts of Cornwall, where they effected a great saving of fuel, and therefore of expense, the coal used in that county being brought from South Wales. It is chiefly to the object of economy that the efforts of late engineers have been directed, and so successfully, that their improvements have fully kept pace with the increasing depth of our mines, many of the most abundant of which would have long since been abandoned had not this been the case. These great improvements have chiefly originated in Cornwall, where ingenuity has been stimulated by the high price of coal; and among the numerous individuals who have contributed to them, the names of Woolf, Trevithick, and Grose may be particularly mentioned.

The improvements in the manufacture of iron which took place in the latter part of the last century, while they vastly increased the demand for it, and thus gave a great stimulus to the working of this metal, and of coal also for its reduction, contributed much to the perfection of mining generally, by enabling the miner to employ iron pumps instead of wooden ones, which were before used. This change allowed a better construction and arrangement of the pit-work, one of the most important apparatus employed in mining, and hence greater depths have been attainable than might otherwise have been the case. Among many minor improvements which may be traced to the same

source may also be mentioned the laying down of iron tram-roads underground in mines, as well as their use upon the surface: the carriage of the mineral to different parts of the works has thus been greatly facilitated and economised.

Simultaneously with the improved machinery and apparatus introduced towards the close of the last century, great improvements also took place in the internal economy of mines and the arrangements of the underground works. The ancient mode of following down the ore by irregular isolated excavations, and of stoping the bottoms of the mines in the German manner, gave place to the present system of laying open the ground for discovery and extraction, by a well-arranged series of shafts, levels, and winzes. By this plan the ore or mineral is divided into more convenient masses for extraction, and can be worked much more economically than by the former mode of stoping or cutting away the ground in the bottom of the levels, as still practised on the Continent.

The most recent improvements which have been introduced into mining are those which regard the mechanical treatment of the ores after they have been extracted from the mine, and previous to their being fit for the furnace. The processes used for this purpose are technically termed “washing” and “dressing,” by means of which the ore is freed from many of its earthy impurities, and thus rendered much richer for metal, in an equal bulk. In effecting this object several kinds of apparatus are employed, chiefly the stamping-mill, the crushing-mill, and the jigg-machine, the use of which has been known from time immemorial; but more attention has latterly been paid to their application, and it has also become far more general, to the great benefit of all mines, especially those in which a large proportion of the poorer ores are obtained. The competition with foreign mines, in which labour can be obtained more cheaply than in this country, has done much to promote this class of improvements, which, though less striking than some others, have, within the last few years, been productive of extremely beneficial effects, and may still be considered as in progress.

The history of coal-mining is in great measure distinct from that branch of the art which we have been tracing, and which chiefly relates to the extraction of the metals. The introduction of gunpowder, the invention of the steam-engine, and the improved manufacture of iron, have formed however epochs of common importance to both, having greatly contributed to the present extended scale upon which our coal-mines are worked. The great objects to which improvement has within the present century been directed are the ventilation of the works and the invention of lamps which should not be liable to explosion on contact with the fire-damp. The system of ventilation in our collieries has been greatly improved of late years by Mr. Buddle and others; and the beautiful and well-known invention of the safety-lamp, in 1815, by Sir Humphry Davy, has afforded the miner a valuable though not in all cases an effectual preservative against explosion. [LAMP, SAFETY.]

One of the most important events in the recent history of mining in this country is the establishment of suitable means of instruction for the mining engineer. This desideratum was first supplied by the university of Durham, which opened a class for instruction in civil and mining engineering, in January, 1838. In the latter part of the same year a similar department was opened in King’s College, London; and a similar institution was organised by Sir Charles Lemon at Truro, in Cornwall, but, unfortunately, it did not meet with the support it so justly merited, and has since been discontinued. The local positions of the Durham University and of the Truro institution were highly favourable to the joint acquisition of theoretical and practical instruction—an advantage in which neither King’s College nor the Government School of Mines in Jermyn Street can participate, although both must afford valuable preliminary instruction to the mining engineer. These various institutions can hardly fail, in time, to produce an important effect on the mining industry of this country.

Mineral Deposits.—In proceeding to treat of the practice of mining, some preliminary details will be useful; for as mining operations are of course in great measure regulated by the nature of the mineral or metalliferous deposits to which they are directed, and by which are determined the form and construction of the mine, and much of its internal economy, it will be necessary briefly to glance at this subject, and to point out some of the most important modes in which mineral masses are presented by nature to our research. Of the various classes into which mineral deposits may be divided, it will be sufficient for our present purpose to notice four only,—*veins, beds, masses, and fragmentary deposits*,—each of which is the repository of vast mineral treasures, but more especially the first two.

Veins have originally been, in most cases, long, narrow, and irregular fissures, traversing the rocky crust of the globe, which they penetrate to an unknown depth, and often at a high angle of inclination. They are for the most part filled with sparry and stony substances, called the “veinstone,” or the “gangue” of the vein, but contain here and there irregular masses or “bunches” of the metallic ores, often of immense size and value, and which it is the principal business of the miner to discover and extract. Most of the metals are of common occurrence in veins, as, in this country, copper, tin, lead, and zinc, to which, in other parts of the world, may be added gold and silver.

Beds are layers of mineral substances interposed between the strata of solid rock, which, except in their containing valuable matter, they

very much resemble. The layers of flint, which may be often seen imbedded in chalk wherever a section of this rock is made, will convey a good idea of a mineral-bed. Several of the metals, especially lead, are occasionally found in beds; coal, clay-ironstone, and rock-salt exclusively so; but the last-mentioned mineral is far less regular and continuous than the former.

Masses, or "pipe-veins," as they are often termed by the miner, are not so easily defined: the best idea which can be given of them is that of an irregular branching cavity descending either vertically or obliquely into the rock, and filled up with metalliferous matter. Deposits of this nature are less common than the two former classes; they usually contain either copper or lead, and some of the rich oxides of iron appear to belong to a similar formation.

Fragmentary Deposits occur associated with and indeed forming part of many of the loose superficial beds of sand and gravel which occur in the valleys of mineral districts, consisting of the detritus of the neighbouring mountains, which has been washed down from thence at remote geographical epochs. The mineral substances found in these deposits, which may be considered as having originally been derived from veins or beds in the vicinity, are not, in most cases, mixed up indiscriminately with the alluvial matter, their greater specific gravity having occasioned them to be deposited in distinct layers by themselves, usually towards the bottom of the mass. Tin and gold are the metals which most commonly occur in deposits of this kind.

Geological Position.—The above-mentioned mineral and metalliferous deposits are not found promiscuously distributed throughout all rocks or soils; on the contrary, there are certain rocks, or rather assemblages of rocks, to which they may be considered as in a great measure peculiar. Granite, porphyry, and the older igneous rocks, generally are metalliferous, and often eminently so; but mineral deposits are on the whole most abundant in rocks of sedimentary origin, and more especially in and near situations where these two classes of rocks (the igneous and sedimentary) are in contact, or where a metamorphic structure has, from the action of internal causes, been superinduced upon the latter. It does not appear that nature has confined particular metals to any exclusive kind of rock, yet traces of a general association may still be perceived. Thus, tin, copper, gold, silver, and certain deposits of iron, are most abundant in the class of rocks usually termed primary; while lead, zinc, mercury, and the earthy ores of iron, are most abundant in the older secondary rocks, which also contain our principal deposits of rock-salt. Veins are of most common occurrence in igneous and primary or metamorphic rocks, in the vicinity of which the derivative fragmentary deposits are therefore most often found. Mineral-beds, although sometimes occurring in primary rocks, are most common in secondary countries; and irregular masses, or pipe-veins, are most strikingly developed in limestone districts, where they probably occupy original cavities in the rock.

Metallic Ores and Mineralising Substances.—The state in which the metals are found, the full consideration of which belongs to chemistry and mineralogy, will next require our attention, so far as it is immediately connected with the business of the miner. It must be well known that the metals are very rarely presented to us in a pure or metallic state, although native masses of copper and iron are occasionally met with; but gold, from its small affinity for oxygen and other mineralising substances, although frequently alloyed, is never mineralised. The great bulk of the metals then, with the exception of gold, are found in the state of *ores*, that is, chemically combined with certain mineralising substances, which completely disguise, and, in fact, till separated by metallurgical processes, destroy their usually recognised and useful properties. The most important of these mineralising bodies are oxygen and sulphur; the next in rank are chlorine, and the sulphuric, carbonic, and phosphoric acids. The mode in which they combine with the metals is in binary compounds. Of the former we have examples in iron, lead, and mercury, which, when mineralised by sulphur, form respectively the following sulphurets, iron pyrites, galena, and cinnabar: we observe the latter in all cases where the metals are mineralised by acids, as in spathose iron-ore, or carbonate of iron, in which one binary compound, the oxide of iron, is united to another element, the carbonic acid. From this naturally compound state, in which the metals almost invariably occur, arises the art of metallurgy, which, although generally considered totally distinct from that of mining, is nevertheless most intimately connected with it.

Earthy Impurities.—Independently, however, of those chemical combinations from which the metals can only be freed by the smelter when treated in the furnace, there are other mechanical impurities scarcely less important, which require to be partially separated on the mine, and which therefore fall entirely within the province of the miner. Although large masses of the metallic ores, as before noticed, are concentrated in bunches or deposits, confined to particular portions of the vein, there is also a great proportion of the ore in all mines, which is more or less intermixed with the veinstone, or often indeed finely disseminated through it; and as the expense of fusing this large mass of earthy matter would greatly exceed the value of the metal which it contains, while on the other hand it forms too large a proportion of the produce of most mines to be thrown aside and rejected, great skill has been shown in all mining countries in contriving mechanical processes for effecting its separation as soon as extracted

from the mine. When this separation has been properly accomplished, the metallic residue, before worthless, can be profitably smelted, to the great benefit of all, more especially the poorer class of mines, while those in which the precious metals are worked are entirely dependent for their existence upon the skill and care with which it is performed. The mechanical impurities here spoken of are often sufficiently obvious even in hand specimens of the metallic ores, which, unless purposely selected from the richest parts of the vein, will often exhibit thin alternate layers of the ore and veinstone, or sometimes irregular masses of ore of different sizes which are completely intermixed with and imbedded in sparry and stony matter, and this must be considered the character of a very large proportion of ores in their natural state. It frequently happens too that ores of a worthless character are mixed up with the more valuable ones; thus, copper and lead are very generally accompanied by iron pyrites and blende, both of which must be regarded as impurities, and therefore separated as far as possible previous to any process in the furnace. The great bulk of the metallic ores, when in their natural situation, constitute in fact a most heterogeneous mixture, in which the really valuable metal exists only in a small proportion, chemically combined with one or more mineralising substances, and completely intermixed with sparry and earthy matter and ores of inferior metals. A proper perception of this fact, which is scarcely noticed in works on mineralogy, is most essential to a right understanding of the art of mining, and of the various ingenious processes which in this and other countries have arisen out of it, having for their object the separation and concentration of the metallic matter drawn from the mine, previously to its being submitted to the action of fire.

Preliminary Mining Operations.—As the construction of a mine, or the arrangement of the underground works, must depend in a great measure upon the nature of the mineral deposit to be wrought, if we refer to the great division of mineral deposits into veins and beds, before noticed, it is evident that this construction must be principally of two kinds, adapted to each of the above cases, independently of the less definite processes adapted to the working of irregular mineral masses and fragmentary deposits. Thus, in working a mineral vein, as in a copper or tin mine, the excavations will be formed either vertically or in a highly inclined position, and pursued laterally, or, as the miner terms it, "upon the course of the vein," while the advanced points tend progressively downwards, or "in depth." In working a mineral bed, on the contrary, taking a coal-mine for example, the principal excavations will be formed horizontally around the pit or shaft by which access is first obtained to the deposit.

As a very large portion of the metallic produce extracted by the miner from the earth, and more especially of the soft metals, copper, tin, and lead, is derived from veins, it is to the former of these arrangements that attention will be first directed. The working of coal and iron is considered hereafter, together with that of those minerals which are found in more irregular deposits. The general view of mining which falls within the limits of this article may conveniently be divided into the following considerations: the discovery of mineral veins or other deposits; the first opening of a mine and subsequent extension of the workings; the machinery and other appendages required by these operations, both underground and at the surface, with a brief notice of the surface works, and of mining economy and statistics.

Works of Discovery.—Mineral veins or beds are seldom visible at the surface of the ground, being generally concealed by the thick covering of diluvial matter which is spread over almost every portion of the globe, and hides from our view the solid rocky strata in which they are enclosed. In some cases however where this covering is partially wanting, they may be distinctly traced at the surface, and still more frequently they are rendered visible by the indentation of excavated valleys, and the channels worn by mountain torrents. The same effect is often produced by cliffs on the sea-shore, where veins occur in that situation, of which there are many examples on the coast of Cornwall.

As mineral deposits however present in most cases no trace of their existence at the surface, certain general indications must be had recourse to for their discovery. The most general of these indications (which can be but briefly noticed here) are furnished by geology, which teaches us that certain metals are most abundantly found in certain rocks, and further points out that they do not occupy any position indiscriminately in those rocks, but are almost exclusively found near their junction with other rocks of a different character, more especially near the contact of igneous masses with sedimentary strata, and that they commonly occur where rocks alternate together, and are broken and dislocated. Thus the tin and copper veins of Cornwall are situated chiefly in a species of clay-slate provincially termed "killas," and either near its junction with protruded masses of granite, or where it is intersected by channels of a porphyritic rock termed "elvan." In Wales and the north of England the lead veins are chiefly situated in the carboniferous limestone and rocks associated with it, especially in places where they are intersected and broken up by enormous faults and dislocations. Similar circumstances to these are very generally observed in all parts of the world, and it is also well ascertained that the local enrichment of veins is greatly influenced by their intersection with one another; and often indeed closely corresponds with the points of junction.

In addition to the general presumptions furnished by geological

science, another and more precise indication of the existence of metaliferous deposits is afforded by finding pebbles or fragments of ore on or near the surface, generally either in the beds of streams or mixed up with superficial detritus. These scattered fragments, the result of diluvial action upon the outcrop of mineral veins or other deposits, may often be traced to particular spots, and thus the position of the deposits from which they originated may be established. In the north of England they are termed "shoad stones," and this mode of discovering veins is called "shoadng." Should the exact situation of the vein whose existence has been ascertained in this or any other manner not be observable, it may be ascertained by opening trenches in the alluvial soil deep enough to expose the solid rock, their direction being at right angles to that in which analogy or the position of other veins in the neighbourhood would render it probable that the vein or veins in question might lie. This mode of finding veins is provincially termed in Cornwall "costeening." The object of discovery may be still more effectually attained, but at a greater expense, by excavating a nearly horizontal passage termed a "level," "drift," or "adit," from the bottom of the nearest valley, carrying it through the solid rock in the direction before mentioned, so as to intersect or "cut" any mineral deposit which may exist in the ground through which it passes. This last plan is however seldom adopted, unless it is previously well ascertained that mineral veins do actually exist there, as it is too slow and too expensive to be undertaken upon uncertain grounds. Discoveries are sometimes made also by driving on the course of veins which occur in cliffs or are exposed in the sides of brooks; trials of this kind fall within the compass of working miners or persons of very small capital, and in some instances form the first step in opening mines which ultimately become of great importance.

Although the manner in which mineral deposits may be and sometimes are originally discovered has been thus detailed, it must not be supposed that the process is one of very frequent occurrence. The principal mineral districts in this and most other countries have been known and explored for ages, and by far the greater part of our mineral produce is extracted from deposits which have long been worked, the principal new discoveries being either made upon untried portions of known veins, or simply by excavating passages or "cross-cuts" from mines now working, in a direction transverse to that of the vein upon which they are wrought, so as to prove the adjoining ground.

Financial arrangements, &c.—When however a new vein or mineral deposit has been by any process discovered, if the indications of metallic produce are such as to render it desirable to work it, the most usual step, after obtaining the consent of the proprietor, is the formation of a company for this purpose. For although mines are sometimes worked by individuals, experience has shown that a company is best adapted for carrying on mining operations, the amount of capital required being large and uncertain, and the risk great, while a long period may elapse before adequate returns are made. Hence, not only in England, but in most other countries, the system of working mines by companies has been adopted, being found decidedly advantageous. Certain stipulations are then entered into between the company and the proprietor of the land in which the vein or deposit is situated, or, should the mineral right not belong to him, with the person who does possess it. The principal terms of this agreement are to determine the extent of ground within which operations may be carried on, and to stipulate the proportion of the gross mineral produce or its equivalent in money which the owner is to receive free of all expense in raising and making it marketable. It often includes also compensation for damage done to the surface, and other considerations of less importance which are determined by the custom of the neighbourhood and other circumstances.

Before commencing operations, it is necessary to ascertain with some correctness (if it should not be previously known) the bearing or direction of the vein, and also its dip or "underlie," which may be done by sinking a few shallow pits upon it. These circumstances being known, there are two methods by which the vein may be explored, either by sinking upon its course from the surface, or by forming a horizontal passage to intersect it, commenced from some neighbouring valley or the lowest point on the surface which may be conveniently situated for the purpose; or both these modes may be carried on together if desirable. As, however, the practicability of forming a level or adit to prove the vein at a sufficient depth and within moderate limits as to time and expense must entirely depend on local circumstances, the former method, as being most expeditious, is generally resorted to, and is effected in the following manner.

Early Progress of the Works.—A spot determined either by convenience or by some promising indication is selected as the site of a shaft, which is frequently sunk in an inclined direction upon the course of the vein, or if intended to be perpendicular it is commenced upon that side towards which the vein inclines or underlies, and at such a distance from its "back" or outcrop as to come down upon it at a given depth, say 10, 20, or 30 fathoms. This depth is regulated by the means of the parties to prosecute the trial, and the depth at which analogy may lead them to suppose that ore in any quantity may be found, the superficial parts of veins being usually quite unproductive.

On cutting the vein the shaft is for a time suspended, and two horizontal passages, often termed "galleries," but by the miner "levels,"

are excavated or "driven" upon the vein in both directions. These passages are usually about six feet in height and three or four in breadth, and rather smaller above than below. They are the principal means of exploring the contents of veins, and are made larger or smaller according to their richness or poverty, their width, and the nature of the inclosing rock. Should the shaft be intended to cut the vein at any considerable depth, it may be desirable to explore it above the point of intersection, and this is done by driving a short transverse level or "cross-cut" to it, and driving two levels from the place where the "cross-cut" meets it, as before described. Should the depth of the shaft before reaching the vein be very considerable, two or three of these cross-cuts will be driven first, and levels extended from them. The perpendicular distance of the levels from each other is regulated both by custom and local circumstances, but is usually about 10 fathoms, that interval having been found most convenient for the objects of the miner.

After cutting the vein there are two modes of proceeding—continuing the shaft perpendicularly through the vein, or obliquely upon the vein. Which of these two plans is followed will depend in great measure upon its produce and promise, as already ascertained by the upper levels, and partly also on the means of the miner, the former plan being most expensive and requiring the longest time, although ultimately most advantageous, while the latter, though a cheaper and quicker mode of exploring the vein, since it renders cross-cuts unnecessary, and is itself continually proving one portion of it, is not well adapted for the application of pumps and machinery,—an evil which may not at first be very sensibly felt, but which increases proportionally with the depth of the mine and the quantity of water and stuff which require to be drawn from it.

Supposing the shaft to proceed perpendicularly after cutting the vein, on reaching the depth of 10 fathoms or thereabouts below the point of intersection another cross-cut will be driven to it; but as the shaft is now on the opposite side of the vein, this cross-cut will have an opposite direction to the former ones; and as they had successively become shorter as the shaft approached the vein, they will now successively become longer as the shaft, proceeding perpendicularly downwards, recedes further and further from the vein. In this manner the shaft proceeds indefinitely, cross-cuts being driven at every 10 fathoms or whatever distance is most convenient, and levels extended from each upon the course of the vein, the nature and value of which are thus thoroughly explored. The continuance of these and other operations necessarily supposes that ore in some quantity has been found in the upper levels, which will have been all this time in progress, or at any rate that the indications of future produce are sufficiently strong to encourage the miner to proceed with his undertaking, the magnitude and expense of which will now be daily increasing, while various difficulties will be encountered in the progress of his works, more especially the want of ventilation in those parts which are most distant from the shaft, by which alone they can be supplied with air. It is chiefly in the ends of the levels that the evil of imperfect ventilation begins to be felt, the air here gradually becoming close and unfit for respiration as they advance further from the shaft, especially when, from the hardness of the ground, frequent blasting is necessary. As soon as this is found to be the case a remedy of a very simple nature is applied, which consists in sinking a small pit, termed a "winze," upon the vein, of course, from the upper level to the extremity of the one below it. This communication having been effected, the two levels become perfectly ventilated, each having a double communication with the atmosphere, by which both an ascending and descending current is produced. By this plan it is evident that the levels may be extended for a considerable distance upon each side of the shaft, winzes being continually formed between them at convenient intervals. Besides the purpose of ventilation, these winzes answer another use, since they make trial of the vein in the intermediate space between two levels, and also divide it into solid rectangular masses, which may be examined all round, and thus the miner has the means of judging with tolerable certainty of the nature and value of the ores contained in each, and can extract the produce in the most expeditious and economical manner. That such is the case will at once be evident when it is considered that these portions of the vein are perfectly drained and ventilated, that they may be attacked at once from as many points as may be convenient or may contain ore of sufficient value, and from this circumstance no necessity exists for breaking down the unproductive masses which are often found to intervene even where the vein is richest and the ore most continuous. When the vein has been properly laid open, the ore may be worked away round such unproductive pieces of ground, which, being left standing, will answer the purpose of supports to the rock on each side of the vein. Where the excavations are extensive such support becomes extremely necessary, and often requires the use of strong timbering.

The utility of winzes for working out the ore is indeed so great, that it is only when little or no ore has been found in a level that it will have proceeded far enough for ventilation to become very defective, before a communication of this kind has been made. When, on the contrary, the ore is found to be tolerably continuous in driving a level, winzes are generally sunk at intervals of 20 or 30 fathoms, their position being so regulated as to prove the richest and most promising parts of the vein, and to avoid hard and unproductive portions which

do not appear worth exploring. We will suppose, however, that a continuous body of ore is met with in one of the upper levels, and that winzes have been regularly carried down to the level below it. Similar operations will then be required here, and winzes will be sunk from it to the next deeper one in the same manner, but they will generally be situated about mid-way between the former, so that each may explore the ground under the middle of the rectangle formed by the two upper winzes and the levels between which they are placed, so as effectually to explore the vein with the smallest number of excavations. The system of works by which a vein is thus laid open, although by no means so regular, is not unlike the seams formed by courses of masonry, the horizontal joints of which may be supposed to represent the levels, and the vertical one the winzes. In cases where the ore extends above the upper level in the mine, this part of the vein may be laid open by perpendicular excavations similar to winzes, but formed in the reverse manner, or by "rising" upwards instead of "sinking" downwards, as

in the former cases, the height to which these "rises" are carried depending on the extent of the ore in that direction.

Should the vein be found to contain ore of good quality and in sufficient quantity, both laterally and in depth, the various operations which have now been described may proceed indefinitely. The shaft will continue to be sunk, cross-cuts driven to the vein at every ten fathoms or thereabouts, levels extended in both directions from them (the upper level being always of course considerably more advanced than the lower, from having been longer in progress), and the ground between them subdivided by winzes as before described. The excavations will now have assumed a regular form, and become what is properly termed a mine, the objects for which they were undertaken having been accomplished, or the contents of the vein thoroughly explored, and its produce, where of sufficient value, rendered capable of being economically and expeditiously extracted. In the accompanying sketch, *Fig. 1*, the state of the works is shown, the shaded portion repre-

Fig. 1.—Longitudinal Section, showing the manner in which the vein is laid open by the level and winzes.

sending the parts of the mine whence the ore has been extracted as described below. *Fig. 2* gives a cross section of the mine, and with the former will completely illustrate the foregoing description.

Fig. 2.—Cross Section, showing the progress of a shaft after cutting the vein.

Raising of Ore.—The operation last named, or the extraction of the ore, will not however have waited the advanced state of the works which we are now contemplating: a certain quantity will have been produced by driving the upper levels and sinking winzes below them, although not forming the primary object of these works; and wherever ore ground was seen in the "back" or upper part of the level first driven, it will early have been pursued upwards towards the surface, and will yield the first returns of the mine. When by the further progress of the works the vein has been divided into the solid rectangular masses before described, the mine will have been brought into an effective state of working, and parties of men will be set to raise ores from all the most productive points. Where the vein is not very hard, the ore may be broken down with the "pick" only, but it is generally necessary to blast it with powder, by which process large quantities are detached from the vein by every shot. In raising ores the men generally work upwards from the "back" or upper part of one level towards the "bottom" of another, and the excavations are so arranged that the ore may readily fall down to the level below them, whence it is carried in tram-waggons to the shaft, and thence raised to the surface. As in all large and well-regulated mines it is desirable to

keep the quantity of ore raised as nearly as possible to a uniform standard, the process of "opening ground," as above described, will generally either keep pace with or even exceed the rate of exhaustion, so that a portion of the ore thus laid open may always be held as a reserve to keep up the returns of the mine during periods of temporary depression, when only poor and unproductive ground may be presented by the works of discovery. This judicious mode of proceeding is justly regarded as one of the greatest modern improvements in the economy of mining: it provides a compensation for those great irregularities and fluctuations to which all mineral deposits are continually subject; it keeps up the returns of the mine during temporary intervals of poverty, and enables those trials to be effected which may again place it in a productive state.

Extension of the Works.—As the workings of a mine become more extended, they gradually lose the simplicity which we have been supposing, and, from the multiplication of shafts and other excavations, become highly complex, a result to which the irregularity of mineral deposits greatly contributes. The nature of these ulterior operations will now be briefly described, still considering the mine as a mere system of excavations, and reserving till hereafter the subject of drainage, support, &c. When the levels have been extended to a considerable distance from the shaft, the ventilation will again become defective, notwithstanding their communication by winzes; the current of air, from the greater distance it is carried, becomes more and more feeble; and this evil is still further augmented by the increasing number of men now employed in the works, the number of candles, and the frequent process of blasting. The expense of the transport of ore and masses of rock and rubbish to the shaft also becomes considerable; and if the prospects of the mine continue such as to warrant the expense, a new shaft must now be sunk on one or both sides of the former. Whether one or two shafts will be necessary will depend on the direction in which the ore is found to extend, and the indications exhibited by the vein; and they will be so placed as to command that portion of it which, for reasons before stated, is without the reach of the former one, which by this time also may have become inadequate for the various purposes of extraction, drainage, and descent, to which it is applied.

In order to avoid the expense and delay of unnecessary cross-cuts, the new shaft will be so placed as to intersect the vein much deeper than the former, and this point will be so arranged as to correspond either with one of the deepest levels, or some proposed level deeper still. The new shaft may have been commenced in anticipation, while the levels were yet distant from the point where it is sunk; and in this case its communication with the mine will have been accelerated by driving levels to meet those which are proceeding from thence towards it. When this communication has been effected, its benefits will be immediately felt, both in the thorough ventilation of the mine and the increased facilities afforded for the extraction of ore and stuff.

As the process of sinking a shaft is often extremely slow, from the

hardness of the ground (one fathom per week being a very good average, and sometimes half that progress being scarcely attainable), and as the most productive workings of a mine may be greatly impeded for want of another outlet to the surface, expedition is often of the utmost importance to remedy this evil, and it thus becomes highly desirable to accelerate the operation. The perfection which subterranean surveying has of late years attained enables the miner to accomplish this object by a very interesting process, whenever the workings of the mine have advanced near the spot where a shaft is required. The site of the shaft having been fixed upon and marked out at the surface, the miner, by a series of very accurate measurements of the length, windings, and direction of the levels, is enabled to ascertain correctly their relative position with regard to this spot, and consequently at what point each of them approaches nearest to a supposed vertical line penetrating the rock below it. This being ascertained, it is evident that by pursuing the same process still further, he may determine in what direction and to what distance cross-cuts must be driven from each of these points, in order to bring him exactly to this line, or underneath the site of the shaft; and having arrived there, that excavations exactly corresponding with it, both in form and dimensions, may proceed simultaneously both upwards and downwards from each cross-cut, while the shaft itself is being sunk from the surface, the work thus proceeding from several different points at the same time, as shown in *Fig. 3*. It is found in practice that the various separate portions may be made to unite with surprising exactness; so much so, that even in very deep shafts, when complete, daylight may be seen from the bottom; and from the great saving of time which the process effects, it is now frequently used in mines of great depth, the working of which is much facilitated by it, as the work of many years may thus be brought within the compass of one or two. A very remarkable instance of a deep shaft being thus sunk from several points at once occurred at the Consolidated Mines in Cornwall, about thirty years ago, where a perpendicular shaft, 204 fathoms in depth, was completed in less than a twelvemonth, being worked from fifteen different points at once.

Fig. 3.—Cross Section, showing the progress of a shaft worked at several points.

As the working of a mine proceeds, the increase of shafts and levels tends to obliterate, in a great degree, the uniformity and simplicity of operations which were at first apparent, the position of these works being entirely regulated by the irregular distribution of the productive parts of the vein, as developed in their progress. When the depth becomes considerable, many of the first shafts are rendered in a great measure useless, either from being inclined, and thus inconvenient for machinery, or from having passed through the vein at a shallow depth, and thus requiring long cross-cuts previous to commencing the deeper levels. Hence, in very deep mines, a double line of shafts will often be found to range along the course of the principal veins; and sometimes even three shafts will be found opposite each other, and intersecting the same part of the vein successively at greater depths. In this case, while the most recent shafts are used for drainage and extraction, the older and more shallow ones are often fitted up as "foot-ways," and serve for the partial ascent and descent of the miners. In some of the large mines of Cornwall it is usual to sink two shafts within a few fathoms of each other, one being of large dimensions, and intended for a drainage or "engine-shaft," the other smaller, and adapted to drawing stuff only. This arrangement is found more convenient than having a single large shaft arranged for both purposes, for which however one shaft is often made to answer, being divided down the middle by timbering, and one side appropriated to the pumps and ladders, while the other is occupied by the "kibbles" or iron buckets used for drawing the ore and in many cases the rubbish, when the latter cannot be conveniently disposed of underground.

Shafts in this country are generally sunk of a rectangular form, except in our coal mines, where a circular form is often preferred.

Those intended for the extraction of ores, or "whim-shafts," are commonly six feet by four; those employed for drainage, or "engine-shafts," as they are generally termed, vary from about six feet by eight to eight by ten, or sometimes are rather larger. In coal-mines the pits are generally about seven or eight feet in diameter, the dimensions varying according to the nature of the ground and the arrangements proposed in them.

As veins are generally found to run nearly parallel, and often at no great distance from each other, and as the neighbourhood of a productive vein is a favourable indication of the contents of others in its vicinity, transverse levels or "cross-cuts" are frequently driven from mines at various depths, with a view to discovering side-veins, or making trial of branches which diverge from the main lode. Should a productive vein be found in the neighbourhood of the first, the most usual mode of working it is by extending levels upon it, at the same depth as those in the mine from which the cross-cuts are driven, commencing at the points where these intersect it. In this case the same shafts will probably serve for both the old mine and the new one, the one being, in fact, a mere appendage, as it were, to the other. Should the distance of the newly-discovered vein be considerable, it will prevent the workings from being carried on in this manner, both from the length of the cross-cuts, and from the difficulty of ventilation and extraction; and it will therefore be necessary to sink shafts upon it, and lay it open as a separate mine, in a somewhat similar manner to that which has already been described.

Metalliferous veins are often traversed by other veins crossing them nearly at right angles, which seldom contain ore, excepting perhaps near the points of intersection: they are termed "cross-courses," or "cross-veins," and occur in most mines. Cross-cuts are sometimes carried upon these veins, partly to explore their contents, and partly because the work will often proceed more rapidly than when in the solid rock; but this is not considered so effectual a mode of exploring the ground and discovering new veins as by driving in the rock itself.

The intersections of veins are very generally accompanied by a shifting and derangement of the metalliferous vein, the two portions of which on the opposite sides of the cross-vein, are often separated to a very considerable distance. As veins are most productive at or near the points where such intersections occur, the metalliferous mass on which the miner had previously been working is completely lost on coming to a cross-vein; and it is frequently a work of considerable difficulty to recover it again, as the productive vein may be thrown or "heaved" completely out of its former course. The first object to be ascertained, in the search for the dislocated vein, is in which direction the "heave" has taken place, whether to the right hand or the left; and from analogy the miner is generally, though not always, enabled to form a correct judgment on this head. He then continues the level upon the cross-vein in this direction, till the metalliferous vein is again met with on the opposite side, when the level is continued upon it as before. If the search should be continued for a long distance without success, he will drive in the other direction, in expectation of meeting with it there.

Adits.—Where a vein has been worked by driving a level towards it from a valley or other convenient point on the surface, the drainage to the point of intersection is, of course, complete; and hence in mountainous countries, where deep ravines occur, levels may be brought in one below another, so as to prove the veins and unwater the mines to a considerable depth, almost superseding the use of machinery for this purpose. Levels thus opening to the surface, and serving for drainage, are termed "day-levels" or "adits," and few mines are without one. In cases where mines have been opened by sinking down from the surface, which is the most common method, an adit is generally commenced from the bottom of some neighbouring valley (see *Fig. 2*), which is driven towards the vein with a slight inclination, so that the water may readily flow through it; and in large mining districts adits have been formed of enormous length, traversing a considerable number of mines, and carrying off the water to the lowest practicable point of drainage. In driving an adit, if the length be considerable before it reaches the mine which it is intended to drain, the distance is often divided into two or more portions by sinking shafts upon its course, and driving from the bottom of each on reaching the requisite depth. The work is thus expedited in proportion to the number of points from which operations may be commenced. Adits may often be made valuable as works of discovery, by making them cross the direction of the veins occurring in the district, so as to intersect them in their course, when they afford the means of trial at a cheap rate, by driving upon them at the points of intersection. In some cases adits may be carried almost entirely upon veins, to which they thus afford an important trial.

It is evident that the shafts and levels may be indefinitely extended in the manner which has now been pointed out, and should the produce of the mine be considerable, the portions of the vein successively laid open continue productive, and other veins be discovered by cross-cutting in its vicinity, this extension of the works may be continued for many years. Thus, in the course of time, from a few simple excavations, we obtain that almost infinite complication of shafts, levels, cross-cuts, and other workings, which characterise the workings of an extensive mine, with all its numerous appendages of pumps, machinery, and buildings.

The operations which have now been described are applicable to all large and regular metalliferous veins situated in countries where no distinct stratification exists, and where, therefore, from the homogeneous nature of the rock, the metallic produce may extend to very considerable depths without any great fluctuation. The mining districts of Cornwall, and those of Germany and Mexico, are chiefly of this class.

Mining in Stratified Districts.—In working mineral veins in distinctly stratified countries, this geological feature has a great influence on the arrangement of the subterranean works, as it impresses a peculiar character upon the contents of the veins, the metalliferous portions of which are in great measure confined to certain strata, while the intervening parts are poor and unproductive. Thus, instead of exploring the whole mass of the vein, as in the former case, it is only necessary to lay open those limited zones which are embosomed in the strata most favourable to enrichment, and to which therefore the workings are chiefly confined. The lead-mines of North Wales, of Derbyshire, and of the North of England, are worked in the carboniferous limestone, and the grits and shales resting upon it, the two former being the productive rocks. In these mines therefore the mode of working above noticed is adopted, and, from the abrupt and mountainous nature of the country, great facility is afforded in carrying on the subterranean works, which are generally executed in the following manner. A point is selected in some valley or ravine where the edges of the strata are exposed to view, and from thence a level is commenced, if practicable, upon the vein itself, and in one of the beds known to be favourable to its enrichment, the progress of which effectually explores its produce, and admits of a convenient extraction of the ore. Should the vein itself not appear in any spot from which it can be directly driven upon, the level is driven as a cross-cut till it is reached, being either carried on one of the productive strata, or in some other bed adjoining them which may afford greater facilities for driving. Whenever bunches of ore are found in the progress of this level upon the vein, excavations are carried upwards and downwards into them, as far as the ore extends, thus laying it open in a convenient manner for extraction. Should the ore extend far enough towards the surface to render it necessary, levels may be driven from the "rises" to render it more accessible, and should another productive stratum be situated at no great height above the first, similar operations will be extended into that also. The vein having thus been laid open, the masses of ore are placed in a proper state for working; they are broken from the vein either by the pick or by blasting, and the works so arranged that the stuff falls at once into the level below, whence it is transported in tram-waggons to the entrance, near which the dressing-floors are usually placed. Fig. 4 represents the section of a mine worked in the above manner.

As the principal level of a mine worked in this manner is always, when possible, carried at or near the bottom of the lowest productive stratum, the whole process of working may often be carried on by rises, and no necessity will exist for sinking below the main level, which answers the purposes both of drainage and extraction. When, however, other productive strata exist below this, which from the nature of the country are inaccessible by day levels, recourse must be had to sinking winzes below it to explore them.

When a level has been driven a considerable distance from its mouth or entrance, a shaft will be required, which is usually sunk from the surface so as to come down upon it near the end. The deeper workings are then carried on by means of this shaft, which is either continued perpendicularly or upon the vein, till it reaches the next productive stratum, upon which a level will be driven. By extending the day level or adit upon the course of the principal vein, and such others as may be found in its vicinity, and by sinking shafts occasionally where they may be found necessary; a mine worked in this manner may be indefinitely extended, and its workings arranged so as to be accommodated to the nature of the metalliferous deposits which may be discovered in their progress.

Although the general principles which regulate the direction of mining operations will best be understood from thus tracing their most important modification from the beginning to a mature and systematic development, it must not be supposed that all mines are invariably worked upon the same plan, or even that the first opening of mines is a thing of very frequent occurrence. The local circumstances of mines are so exceedingly various, and the irregularity and complexity of mineral deposits so great, that a corresponding diversity must exist in the means adapted for exploring them, and hence,

although the general principles and features are the same in all, no two mines will be exactly alike, nor would the same unvarying processes be suitable for them.

Mining Tools and Processes.—The tools and processes employed by the miner in the excavation of the rock or the vein are simple, and will require only a brief notice. As his work is chiefly of two kinds, simply *excavating* the ground when soft, and *blasting* it when hard, his tools are suited to each process, the "pick" and "gad" being used for the former; the "borer" or "jumper," and the "hammer" used to propel it, for the latter, with several minor accessories for firing the shots, when the hole has been completed to its proper depth. The *pick* is a very useful tool and much employed by the miner both in working in the rock and in breaking down ore where the ground is not so hard as to require blasting. It resembles a common pickaxe, but is smaller and more convenient, the iron head being sharp and pointed at one end, and very short and hammer-shaped at the other, a form which peculiarly adapts it to underground uses. The *wedge* or "gad" is sometimes used in conjunction with the pick; it is made of wrought-iron, and often with curved sides. The *borer* or "jumper" is an iron rod or circular bar usually about two feet in length, steeled and formed into a flat sharp edge at the end; it is driven into the rock by one man with a heavy hammer, while the other continually turns it round so as to expose the cutting edge to fresh surfaces of rock. The pulverised matter is drawn out from time to time by a tool called a "scraper," and when the hole has proceeded to a sufficient depth, and been charged with powder, an iron wire with a copper point, or, what is still better, a piece of copper wire, with a loop at the end, is introduced, when the charge having been firmly rammed down with clay or other soft mineral substance, the wire or "needle" is withdrawn, and a train of gunpowder inserted in its place. The train is then fired by a slow match (often a piece of brown paper smeared with grease), and the miners retire till the explosion has taken place. A very ingenious contrivance for firing the charge was invented some years ago in Cornwall, by Messrs. Bickford, called the "safety fuse," which is now getting into very general use in our mining districts. The safety fuse consists of a small train of powder inserted in a water-proof cord, and being cut to the required length, regulates the time of the explosion by its known and steady rate of ignition. The use of this contrivance and the substitution of copper for iron in the "needle," have contributed of late years to prevent the accidents arising from premature explosion, which were formerly of very common occurrence in mines.

Auxiliary operations.—Having now considered mining in the most simple point of view which the subject admits—as the arrangement of a system of subterranean works adapted to effect the great objects of discovery, extraction, ventilation, and drainage, it remains to notice the various auxiliary operations which the progress of these works will have required, and the complicated machinery which will thus have been called into action, both on the surface and underground. The auxiliary works in question will have been directed towards two distinct objects, one portion of them being subsidiary to the actual working of the mine itself, and the other directed to the mechanical preparation of the ores extracted, so as to render them fit for the smelting works, to which they are finally consigned for reduction, this last process being sometimes carried on upon the spot and by the same parties, and in other cases being performed at a distance by a distinct agency. We now proceed to consider the former of these two classes.

The underground works of a mine will not have proceeded far before it becomes necessary to provide for several very important contingencies; water filters rapidly in, and, excepting where mines are worked by day levels or adits (or even then on sinking below them), requires some power to be provided for drawing it out; excavations are formed which require support; ventilation in places requires to be aided by mechanical means; and lastly, the continually increasing extraction of ore and rubbish renders powerful and efficient means indispensable for its discharge.

Drainage; Horse-Whim.—The drainage of a mine is one of the earliest things which it becomes necessary to provide for, as mineral veins are generally more open and porous than the surrounding rock, and thus form natural reservoirs into which the surface water collects. When penetrated by the workings of a mine, this natural drainage is rendered still more complete, and water pours abundantly into the excavations. The most obvious mode of relief, where local circumstances are favourable, is of course the formation of an adit, but excepting in very abrupt and mountainous countries, where this work can be readily executed, mechanical power soon becomes necessary. This may be in the first place afforded merely by a "horse-whim," which will serve to raise both the water and the stuff broken in sinking; and in Mexico, before English skill and capital were applied to the working of the mines, this simple apparatus was the only power used in their drainage and extraction. Its application on the large scale is however so enormously expensive, so complicated, and so inconvenient, that in the mines of Europe it is only used upon a limited plan, and mechanical power is substituted as soon as possible for animal labour. The machine alluded to consists of an upright shaft carrying a large cylindrical cage or drum, and turned round by a long lever, to which the horses are attached. A rope is coiled round the cage of the whim, with both ends at liberty, so that while one end is winding up, the

other is unwinding, and both pass over a pulley placed above the shaft, having large iron buckets or kibbles attached to them, which by this arrangement are kept alternately ascending and descending, one kibble being loaded at the bottom while the other is emptied at the surface. This apparatus is termed a "whim" in Cornwall, but in the north of England a "whimsey" or "gin." Where mines are not very deep it is a convenient auxiliary in the extraction, but is only useful for drainage when the quantity of water is very trifling, as in sinking a mere trial shaft. (See Fig. 5.)

Fig. 5.

Water-wheel.—When the influx of water in a mine becomes at all considerable, recourse must be had to the power either of water or of steam to discharge it to the adit, or the surface, as the case may be. Should local circumstances be favourable to the application of water-power, it will of course have the preference, being recommended both by its economy and steadiness of action. The nearest stream of water available for this purpose will be turned into an artificial watercourse, or "leat," and conducted to the mine so as to obtain a sufficient fall to turn an overshot water-wheel, whose diameter and width will be regulated to receive it. Where a constant and abundant supply of water can be obtained, this power becomes extremely valuable, and the miner avails himself of it with great ingenuity, constructing large reservoirs in the valleys through which the stream passes, to render the supply more equable in time of drought, and erecting as many water-wheels on the mine, each receiving its supply from the tail of the other, as the declivity of the ground will admit. The water-wheels used in mines are invariably overshot; they vary from 10 or 12 feet in diameter to more than 50 feet, and from 2 or 3 to 6 or 7 feet in breast: some of the largest exceed 100 horse-power. The German miners have long been celebrated for their skilful application of water-power which, from the mountainous nature of their mining districts, early presented itself to their notice. In this country, from the general application of the steam-engine to the drainage of mines, water-power has been less cultivated; but many fine instances of its use may be seen in some of our mines, where circumstances have been favourable to its adoption. Among these may be named the Fowey Consols Mines in Cornwall, the mines of Wheal Friendship and Wheal Betsy in Devonshire, and of Grassington in Yorkshire. The application of a water-wheel to the drainage of a mine is shown in Fig. 6.

Fig. 6.

Pumps.—During the erection of the water-wheel pumps are fixed in the shaft, proportioned in size to the quantity of water to be drawn, 10 or 12 inches in diameter being a very common size, where there is only a moderate influx. The pumps used in mines do not act at all by atmospheric pressure, as in the case of the common household pumps; they are arranged in "lifts," or columns, of considerable height, often indeed from 20 to 30 fathoms, the water being discharged into cisterns placed at the foot of each, and raised entirely by lifting or by pressure. The construction and arrangement of the pump-work

forms a very important branch of mining, and one which, from the great depth of our mines, and the vast influx of water so common in them, has been much cultivated in this country, and consequently brought to great perfection. Wooden pumps were formerly common in mines; but they have for a long while been entirely superseded by iron ones, which admit of the lifts being carried to a great height without leaking, or the danger of bursting. The whole column of pumps in a shaft is commonly worked by a single pump-rod, which goes down the middle of it and communicates with each column by a rod attached to its side. In order to give a reciprocating motion to the main pump rod, a crank on the axle of the water-wheel is attached to one end of a horizontal rod, the other end of which is fixed to an apparatus termed a "bob," consisting of an upright post moveable on a centre, and firmly braced to a horizontal piece framed into it at the bottom, the further end of which is connected with the pump-rod. In this manner it will be seen that the rotatory motion of the water-wheel is converted into a steady reciprocating motion when communicated to the pump-rod, the weight of which is always counterbalanced by a large box filled with stones, old iron, &c., which is attached to the opposite end of the balance-bob. (See Fig. 6.)

As the power of the water-wheels used in mines is entirely due to the gravity of the water, or the force it exerts in falling through a given space, minus the effects of friction, it is only where a considerable stream can be obtained that water-wheels of sufficient power can be erected; but in cases where the supply of water is very limited, and it is practicable to obtain a considerable fall, there is another very ingenious mode of applying it, by which the principle of hydrostatic pressure is called into action. This contrivance is termed the "water-pressure engine," and is a good deal used in the German mines, though only to a limited extent in this country. The principle consists in giving motion to a piston by the alternate pressure of a high column of water, which having performed its office, the communication is cut off, and the water in the cylinder escapes. The apparatus is not in fact unlike the working portion of a steam-engine, the hydrostatic pressure of a column of water being substituted for the force of elastic vapour and the reciprocating motion thus produced may be directly applied to set the pumps of a mine in action.

Steam-engine.—From the great abundance of coal which exists in this country, and the cheap rate at which it can be generally obtained, the steam-engine has long been the great auxiliary of the English miner, and in its present improved state it has greatly contributed, as before noticed, both to the perfection of our mining system and the enormous extraction of minerals and metallic substances by which our mines are distinguished. In our coal-mines, where the fuel is of scarcely more than nominal value, the steam-engine is the only power ever employed for drainage, and in all deep and extensive works for extraction also. In our copper, tin, and lead mines, on the contrary, where the carriage of coal renders the use of it more expensive, water-power is always, as far as possible, rendered available. In all the deepest and most extensive mines of this description the steam-engine is however indispensable, and both the drainage and extraction have been in great measure performed by it, since its use has been so greatly economised by the reduced consumption of coal consequent upon late improvements.

The history and progressive improvements of the steam-engine are so intimately connected with its general application to mining purposes, and consequently with the present perfection which the art of mining has attained, and the vast produce afforded by our mines, that it requires some brief notice here. The efficiency of a steam-engine for mining purposes is estimated in Cornwall (where from the great expense of coal, all the late improvements have originated) by the standard termed *duty*, which accurately and conveniently defines the work performed, with reference to the consumption of a given quantity of coal. Thus, by the duty of an engine is expressed the number of pounds (always millions) of water which have been raised through the height of one foot by the consumption of a bushel of coal, the data for this calculation being the quantity of water discharged from the pumps in a given time, and the quantity of coal consumed by the engine in the same period. This mode of calculating the efficiency of steam-engines was practised by Watt, who thus estimated the saving of fuel effected by his engine compared with the atmospheric engine previously in use, one-third of this saving being the remuneration claimed by him for the use of his invention. An admirable system for the registration of the duty and other peculiarities of the engines employed in Cornwall was organised in the year 1813, and this system has been ever since continued, the results being monthly ascertained and published in a convenient form. The effect of this system has been to excite an extraordinary degree of competition among the engineers, each of whom strives to improve the duty of his engines in every possible manner. The improvements which thus resulted were so unexpected and so extraordinary as to excite suspicion and incredulity among those engineers who resided in other parts of England, which have only been removed by the most rigorous scrutiny and experiments.

The progressive improvement of the duty of steam-engines has been very accurately traced by Mr. John Taylor, in his 'Records of Mining;' and the following is a summary of the results which he obtained:—

In 1769	the old atmospheric engine, by consuming a bushel of coals, raised	5,500,000 lbs., 1 foot high.	
„ 1772	as improved by Smeaton	9,500,000	„
From 1778 to 1815	the steam-engine as improved by Watt	20,000,000	„
„ 1820	as improved by the Cornish engineers	28,000,000	„
„ 1826	„	30,000,000	„
„ 1827	„	32,000,000	„
„ 1828	„	37,000,000	„
„ 1829	„	41,000,000	„
„ 1830	„	43,350,000	„
„ 1859	„	about 54,000,000	„

The above statement, it should be observed, refers only to the average duty, many of the best engines having always greatly exceeded this; and at the present time the duty of the best engines in Cornwall varies from about sixty to eighty millions. In the latter case therefore one bushel of coal performs as much work as fifteen bushels effected seventy years ago, or as was accomplished by four till within the last five-and-forty years. When it is stated that some of the most powerful engines in Cornwall consume from three to four thousand bushels of coal per month, that some mines employ several such engines, and that the mere expense of drainage is 12,000*l.* or 13,000*l.* per annum, the importance of the improvements above noticed will at once be appreciated.

Independently of the vast and practically unlimited power which the steam-engine places at our command, it may be considered as universal in its application, and entirely unrestricted by those limitations of local circumstances which circumscribe the utility of all other modes of drainage. The steam-engine may be erected on any spot which convenience requires, and it may be made of whatever degree of power may be considered requisite; fuel and water alone are needed for its operations; and while successive improvements have reduced the former to a fraction of its earlier consumption, it can always supply itself with the latter from the ground. This independence of local circumstances is of the more importance to the miner, as it is not in his power to make choice of localities: the manufacturer may erect his mill wherever water-power is abundant for driving his machinery, but the miner must carry on his operations on whatever spot nature has deposited her mineral treasures, and make the best of circumstances over which he can have no control. Thus the steam-engine smokes in the narrow valleys of Cornwall, almost at the sea-level, on the verge of the cliff at Botallack, and on the elevated table-land of Mexico.

The steam-engines employed for drainage are erected close to the shaft in which the pumps are fixed, which is called the "engine-shaft;" one end of the beam hangs over the centre of it, and is attached to the pump-rod, which is raised at each stroke of the engine, afterwards sinking with its own weight, which is always counterbalanced by a "balance-bob," as before explained, so that the whole power of the engine is exerted in raising the column of water in the pumps. The engine is generally enclosed in a large substantial building, either two or three stories high, which affords convenient access to every part of it. The centre of the beam is supported by the front wall of the house, and a low building attached to it contains the boilers, which in Cornwall, together with the steam-pipe and cylinder, are carefully cased and covered up with some non-conducting substances. The arrangement of the engine, with that of the "capstan" and "shears" used in raising and lowering the pit work, is shown in *Fig. 7*. The

Fig. 7.

engines employed in draining mines have generally cylinders of not less than 40 inches in diameter, and the cylinders vary from that size to a diameter of 80 or 90 inches, the latter being the largest size ever constructed, and estimated at 300 horse-power. The chief peculiarities of the Cornish engines consist in using high-pressure steam (40 or 50 lbs. to the square inch) expansively, by cutting off the communication with

the boiler at one-fourth or one-fifth of the stroke; in allowing a short interval between each stroke for the perfect condensation of the steam, and in carefully preventing the radiation of heat from the boiler, cylinder, &c. The engines employed in our collieries present no peculiarity worthy of notice, nor has any great attention been paid to their improvement, owing to the cheap rate at which they can be supplied with fuel.

Support.—The support of mines is the next subject which requires our attention, and the extent to which it is necessary will depend very much on the nature of the inclosing rock, which may be either so hard as to stand of itself, or so soft as to crush together unless the excavations be properly secured. The mode of support used in mines is of three kinds: by leaving pillars of the vein, as before noticed, for which purpose the poorer masses are of course selected; by timbering; and by walling either with brick or stone. Timbering is a very common and convenient plan, and is thus practised:—In the case of a shaft, four pieces of timber of the requisite strength are framed into each other and fixed within it at intervals of about four feet apart, the intermediate ground being supported by driving thin boards between each set of timbers and the rock. Levels are supported by three pieces of timber placed in the form of a doorway, rather narrower above than below, and framed together at the top (see *Fig. 8*), the ground between

Fig. 8.

each of these doorways being supported in the manner above noticed. Shafts and levels are sometimes also supported by walling, and in coal-mines the pits are generally lined throughout with brickwork. The "gunnies," or large open excavations from which the ore has been taken, are kept open by strong pieces of timber placed across them, and pressing against the two walls of the vein, which they thus prevent from closing together, as might otherwise be the case, especially where the vein was much inclined, and the pressure of the unsupported hanging wall is consequently great. These open spaces are very useful for disposing of the deads and rubbish which are continually accumulating underground when the workings are carried on in the rock or in unproductive parts of the vein, and which it would be useless and expensive to raise to the surface. For this purpose a "stull" is formed by placing strong timbers in the backs of the levels, upon which boards are laid, so as to form a close covering on which the deads and attle (or rubbish) are then thrown, till the space above has been completely filled up. The pressure of this mass gives it sufficient solidity to support the walls of the vein in an effectual manner; but notwithstanding the large quantity of rubbish thus disposed of in mines, a great deal always remains to be taken to the surface, as the waste heaps on the surface of every mine will show.

Ventilation.—The ventilation of mines is more generally and more effectually accomplished by a judicious arrangement of the works and frequent communication with the surface than by mechanical means, although it sometimes becomes necessary to resort to the latter. It will be evident that in mines constructed on the principles which have previously been explained, the disposition of the shafts, levels, and winzes is such that the entire workings will always be traversed by currents of fresh air, and it is only in particular cases where circumstances prevent the sinking of a shaft in places where it may be required, or where great delay is experienced in effecting the usual communications, that any mechanical process of ventilation is rendered necessary. A very efficient machine for this purpose was invented some years ago by Mr. John Taylor. It consists of a cylindrical exhausting apparatus, which may be fixed at the mouth of a shaft or level, and placed in action by any convenient power, when, by means of a series of tubes connected with it, the foul air is extracted from the interior of the works, and of course the pure atmospheric air rushes in to supply its place, and complete ventilation is thus effected. In sinking shafts, a very simple contrivance is often found sufficient:

small wooden pipes made tolerably air-tight are fixed in the pit from near the bottom to six or seven feet above the top, terminating in a funnel-shaped wooden box, which is moved round so as always to face the wind. The air rushing in passes down the pipes to the bottom of the shaft, in which a constant current is thus kept up (see *Fig. 5*). When levels have to be carried to any great distance without any communication with the atmosphere, they are sometimes divided by a "sollar," or wooden platform placed a foot or two above the bottom, and in this manner a sufficient current of air is obtained to enable the miners to proceed. In the north of England a contrivance called the "water blast" is often used in driving long levels into rising ground; it consists in putting down either a bore-hole or small shaft near the end of the level, and turning a small stream of water into it, which falls into a cistern placed at the bottom, and is found to carry with it a sufficient current of air to ventilate the works. In coal-mines the ventilation is much more difficult, and, from the rapid generation of explosive gases, more important also. It is generally effected by two shafts, one of which is called the "downcast" and the other the "upcast" shaft, the latter of which occupies the highest situation with reference to the dip of the coal, and has a large furnace continually burning near the bottom of it. The air being considerably rarefied at this point, an ascending current is formed, which passes upwards to the surface through the upcast shaft with considerable velocity, causing a descending current to pass through the downcast shaft to supply its place, and by a very ingenious arrangement of the workings this current of pure atmospheric air is made to traverse every part of the mine in succession as it passes from one shaft to the other.

Extraction.—The extraction of the materials from mines will require but little notice here, since it may be stated in general terms merely to require the adaptation of an efficient prime mover to any convenient form of winding apparatus: a purpose for which the steam-engine is very usually employed, although where water-power can be obtained it is equally effective. The horse-whim, or gin, as already noticed, is very useful in small mines or isolated workings, and before the introduction of more powerful machinery was very extensively employed for raising ore and stuff from our mines. In shallow preliminary excavations the common windlass is often employed, and in underground work is much used for various purposes, especially in sinking winzes, and raising the stuff from workings where no regular communications have been opened. The extraction of an extensive mine is enormous: indeed the quantity of ore raised is seldom more than one-third or one-fourth, sometimes indeed a fifth, or less, of the mass of stuff which is brought to the surface. At the Consolidated Mines in Cornwall, the daily extraction is about 200 tons, a large proportion of which is raised from a depth of from 200 to nearly 300 fathoms. In the coal-mines in the north of England the extraction is still greater; but here nearly the whole of the mass raised is more or less valuable, coal-mines being much less incumbered with dead or unproductive works than those of the metals. The South Hetton Colliery, in Durham, sends about 600 tons of coal "to bank" daily, and is capable of affording a much larger extraction.

Mechanical Preparation of Ores, or Dressing.—Having now traced the nature and progress of those subterranean works by which access is obtained to mineral and metalliferous deposits, and their produce extracted, we may briefly glance at the mechanical processes of separation, technically termed "dressing," which fall within the province of the miner, and to the carrying on of which a large portion of the surface-works of every mine is devoted. The object of dressing is to separate as far as possible the earthy matter accompanying, and, as before noticed, often mixed up with the ores, from the metallic portion, which is alone valuable; and the great principle upon which all the varied apparatus and processes which are used in different mines, and in different countries, to effect this purpose, entirely depend, is the difference in specific gravity between earthy and metallic matter, the one being generally double that of the other.

The dressing-floors of a mine are always arranged as near the mouths of the principal shafts and levels as possible, the ore being conveyed to them by a small railway; and they are always provided with an adequate supply of water by an artificial channel or "lead." The floor itself is paved, and there are on one or two sides ranges of sheds for the persons employed to work in, and buildings containing the apparatus used in the operation, which commences by picking the ore, which is brought from the mine in large irregular lumps, as blasted or broken from the vein. These lumps, of which more than half is often merely spar and veinstone, are broken into smaller pieces with hammers, an operation commonly performed by boys and young women, when a good deal of the sparry matter is picked out by hand and at once rejected: the residue is moderate-sized pieces of ore, more or less mixed with veinstone, and often nearly free from it. From rich veins a large proportion of the ore is obtained in a very pure state, and in this case it is only necessary to break down the large irregular masses into small fragments of a pretty equal size, in order to render it marketable and fit for the furnace, there being no earthy or sparry matter to separate from it. This rich ore is immediately therefore arranged in circular heaps upon the dressing-floors, containing a certain number of tons each, commonly fifteen or twenty, and in this state it has much the appearance of fine metallic gravel. The poorer class of

ores, after being broken by hammers, and partially separated from the matrix by picking, have still a great variety of manipulations to undergo, which depend on the nature of the metal and the quality of the ore itself. Of these processes it will be sufficient here to notice three, "crushing" or "grinding," "jigging," and "stamping," each of which is performed by an appropriate machine. The crushing-mill, or grinder, consists of one or more pairs of iron rollers, placed within a very short distance apart, and kept in motion either by the direct action of a water-wheel or by cog-wheels attached to it. Immediately above the rollers is a hopper, into which the lumps of poorer ore are thrown, when, falling through between the rollers, they are completely crushed into small fragments. In some crushing-mills there are two or three pairs of rollers, those below being placed very near together, so as to reduce the stuff falling from above still finer, and by an ingenious application of sieves, kept in motion by the machine, the stuff can be sorted into two or three different sizes. Although by passing through the crushing-mill the ore, with its accompanying veinstone, has been reduced to very small fragments, the two substances are still as completely intermixed as ever; but in the next process, by the jigging-machine, or "brake-sieve," they are, to a considerable extent, separated. This machine consists of a wooden frame, open at the top, and provided with a strong screen, or iron grating, at the bottom: it hangs over a cistern of water, being suspended to a long lever, the motion of which alternately plunges it into the water and raises it out, with a peculiar jerk each time. The ores being placed in the sieve, and subjected for a short time to this operation, the heavy metallic pieces settle at the bottom, while the lighter fragments of spar and veinstone are thrown to the top, and every now and then very dexterously skimmed off with a piece of board by a man who stands by. In the operation of jigging, a very important separation is thus effected, as three products are obtained by it—the small rich particles of ore, which pass through the sieve into the cistern below, and are removed occasionally, as may be necessary; the larger rich fragments, which occupy the bottom of the cistern; and the poor earthy matter, which forms a layer at the top. This last product, although poor, still contains too much metal to be lost: it consists of small fragments of rock or veinstone, many of which have small particles of ore either attached to them or intermixed with them, and, to any eye but that of the miner's, would appear quite worthless, no less from the small quantity of the ore than the manifest difficulty of separating it from such a mass of stony matter. To extract the ore from this refuse matter, several processes are used, which are chiefly grinding between rollers placed very close to each other, stamping to a fine powder by the stamping-mill, and finally, washing upon an inclined plane. In this operation the fine metallic mud or "slime," being carefully spread over the inclined plane at the upper end, a gentle stream of water is allowed to flow over it, which washes the light earthy particles towards the bottom, leaving the heavier metallic ones in a very pure state towards the top. As in this process, and indeed all other operations of dressing in which a stream of water is employed, many of the smallest and most minute particles of the ore are carried away by it, the waste of which, in an extensive mine, would be considerable, it is arranged that all such water shall pass into successive reservoirs, termed "slime-pits," in which the metallic particles fall to the bottom, and are from time to time collected and subjected to such treatment as to obtain them in a tolerably pure state, as a good deal of earthy slime is always deposited with them.

It will be seen from the preceding notice that by repeated pulverisation, washing, and agitation, the metallic ores may be obtained at length in a very pure state, the earthy matter with which they were originally intermixed being by these processes almost entirely separated from them. When subsequently placed in the furnace, this residual earthy matter becomes fused together with limestone, used as a flux, and forms the vitrified matter termed "slag;" while by continued heat, the sulphur, oxygen, and other mineralising substances, which are in a state of chemical combination with the metal, are entirely driven off, and the latter obtained in a pure state. These operations constitute the process of metallurgy.

Variations of the Process.—Any further detail on the subject of dressing would here be out of place; yet it is necessary to observe that different ores require different processes, and that the general outline indicated above is thus subject to considerable modification. In the case of tin ore, which is very intimately disseminated in the rock or veinstone, a very minute pulverisation is required: hence stamping is most extensively practised in our tin-mines; and as the ores of this metal may be dressed so as to give a produce of 50 or 60 per cent., very great attention is paid to this point, and the various manipulations are carried on with a greater degree of attention than in the case of other metals. In the case of copper ores stamping is less used, but jigging forms a very important process, and has consequently undergone great improvements of late years, having given rise to a very ingenious and useful invention, called the "patent separator," in which the sieve is stationary, but the water kept in motion. This contrivance was invented by Mr. Thomas Petherick, manager of the Fowey Consols Mines in Cornwall, where it was successfully brought into operation. The ores of the precious metals require also a peculiar treatment, being generally in a state of minute subdivision, and mixed up with a vast mass of earthy matter. Gold ores are usually

stamped, and silver ores ground to an exceedingly fine powder; but from the great value of the metals, the process of washing is carried on differently from that of others, and, in some cases, is dispensed with altogether.

Management and Internal Economy of Mines.—Having now taken a general view of mining operations, and the auxiliary processes which they require, there is still an important branch of the subject which requires some notice, the management and internal economy of mines. As it is on the due regulation of this point that the success of mines in a very great degree depends, it has, both in this and other countries, received great attention, and been reduced to a system as perfect as possible. In England, more especially, all the practical improvements suggested by experience as essential to the profitable and well-regulated existence of large mining establishments have been freely adopted, as we are here unfettered by those formalities and restraints which influence the continental systems, individual interest being allowed unlimited scope. The nature and importance of the subject now under consideration cannot be better expressed than in the words of a gentleman of the highest eminence as a mining-engineer, Mr. John Taylor, who has thus treated it, in connection with late mechanical improvements in the art of mining:—

"Important as the improvements are which we have contemplated in the instruments which the progress of physical science has placed in our hands, those which relate to the government of large bodies of workmen, to the inducement to active enterprise on the part of the labouring miners, to the removal of difficulties in their way, or of placing them in circumstances most favourable to effective exertion, are even more important, and to this may be added the judicious application of those very inventions which have been noticed. It must be recollected that, after all, the great expenditure in mining is for manual labour, and that we have no means as yet devised for penetrating the rocks which contain mineral treasures but those afforded by the patient and unremitting labour of a great number of men. The regulation therefore of this force, and its due application, is, after all, more important to the success of mines than even the most ingenious mechanical expedients. As an army would undoubtedly fail, however well provided with the most perfect artillery and all the best constructed implements of war, unless the men of which it might be composed were well directed, their efforts well combined, and their courage well assured by reasonable prospects of success, so in mining we may collect and apply the most complete mechanical arrangements; but if the greater power of manual labour be not wisely directed, no beneficial results can be expected."

System of Tutwork and Tribute.—Such being the leading features of mining economy, we may proceed briefly to consider the manner in which they are practically carried into effect, more especially in the deep and extensive mines of Cornwall, where, both from the amount of capital and the number of men employed, every exertion has been made to perfect the mining system, the results of which have since been extended from thence to other parts of England. All the underground work of mines in Cornwall, and indeed of most other districts, is of two distinct kinds:—dead work, or that carried on in the rock or metalliferous deposit, for the purpose of trial and discovery; and productive labour, which is employed in the actual breaking down and extraction of the ore. Now it is in the performance of the immense amount of manual labour requisite in these operations, and in the subsequent process of dressing the ores, that the great expenditure of mining consists; and the great merit of the Cornish plan lies in performing the whole by a system of contracts, which effectually unite for a time the interests of the miner and his employer, while, being renewed at moderate intervals, it continually allows of that re-adjustment which the fluctuating circumstances of the mine may require. The dead work is denominated "tutwork," and the raising of ores "tribute;" these two species of employment being, by an excellent division of labour common in all mines, kept entirely separate and performed by different individuals, who thus acquire great skill and judgment in their peculiar occupations. The mode of payment adopted in tutwork and tribute is entirely different: in the former case, where the miner is employed in sinking shafts, driving levels, &c., the object being to extract as much useful labour as possible from him for a given sum, he is paid at so much per fathom, according to the work done; in the latter case, where the quality of the ore raised is a consideration equally important with its quantity, the miner receives a certain per-centage on the actual value, being paid at the rate of so many shillings in the pound upon that value. The excellence of the above principle will readily be seen; and its advantages are still further increased by the open and public manner in which the contracts are made between the men and their employers, thus allowing of free competition as regards the former, and proving an equally effective check against oppression from the latter.

The usual period for making new arrangements with the men is at the end of every two months, when, all previous bargains having expired, both parties are again perfectly free to regulate their contracts. Previously, then, to this day, every part of the mine is visited and inspected by the underground agents, who afterwards consult together, and determine their plan of operations for the next two months, registering in detail the work to be performed, and what they consider as a fair price to be paid for each separate item. On the day appointed

for the "setting" or "survey," as it is termed, the men who usually work in the mine, together with others who may wish for employment there, assemble round the mine-office, upon a small covered platform, in front of which the agents, at the appointed time, make their appearance with a book in which their previous examination has been registered. Every piece of work to be performed in the mine is then called out in succession, and accurately defined, and the men make at the time a proposition for working it on certain terms. The price thus offered is, in the first place, usually more than would be fair, or than the men themselves expect to get; consequently, the moment a price has been named, another offer will be made somewhat lower, and so on till fair terms have been proposed, when the competition (except in rare cases) will cease, and the work or "bargain" is considered as taken by the last and lowest bidder, whose name is immediately registered opposite to its description in the setting-book. As each piece of work will require the labour not of one individual but of many, the transaction is still further simplified by the bargain being taken and the contract made with one person only, each gang of men accustomed to work together always selecting one of their number to represent and act for them on these occasions. It is evidently desirable that there should be some plan for binding the men to their engagements, so that they should not be capriciously given up previous to the expiration of the term; and this is the more necessary, as, owing to the frequent fluctuations of richness or of hardness incident to the vein or to the rock in which they may be working, they may find themselves unable to realise the amount of wages which they had anticipated: sometimes indeed the change may be so great, that it is not worth their while to go on with it at all. To meet these contingencies there is in most large mines a printed set of regulations, to which all the miners working there must subscribe; and by which fines are established for the non-fulfilment of contracts, sufficiently heavy to prevent them from being given up while any fair probability exists of their being completed at any reasonable rate of remuneration. In this manner the exertions of the working miner are called into action, and prompted to surmount many of the minor obstacles and fluctuations which often baffle his calculations. Although it may appear harsh to exact a fine when a losing piece of work is given up, it must be remembered that, on the other hand, the vein will often improve in quality instead of deteriorating; and in that case the miner will be greatly benefited, as his labour will be employed upon rich ores at the same high rate of payment that was bargained for poorer ones; and from this favourable change he may benefit as much as the exertions of himself and his co-partners will allow, till the fixed time for the renewal of the contracts again comes round. The set of regulations before alluded to prescribe such other rules and fines as are found necessary for the proper management and conduct of the men; and by means of this simple code, the results of mutual and acknowledged interests, it is found in practice that the necessary discipline can be kept up over the large bodies of men employed in our most extensive mines.

Superintendence.—The mode of superintendence by which the foregoing system is kept in due check is very simple: the principle of self-interest which pervades the whole renders unnecessary much of that minute control which would otherwise be needed. The business of a mine naturally divides itself into several departments—the underground operations, the pit-work and machinery, the dressing and surface-work, accounts and financial matters, and lastly, the general control. For each of these departments proper agents or superintendents are appointed, all being subordinate to a general manager, who communicates and advises with the whole body of the shareholders or "adventurers" at stated periods, or more commonly only with a select committee chosen by them, the whole body meeting but once a year. It may be observed that the agents of a mine are usually chosen from the most intelligent working-miners, who are peculiarly well qualified by their thorough practical knowledge both to form a sound judgment upon the state of the works, and to keep a check upon any frauds which might be attempted by the men, while this selection affords a powerful stimulus to good conduct among them, since it may be attended with such advancement. The general control of extensive mines is of course confided to men of superior education and ability, by whom scientific attainments are brought to the aid of the practical knowledge which superintends the inferior departments.

Education and Qualifications of Miners.—We may conclude this article by a few remarks on the education and qualifications of miners, and upon those institutions which have been established with a view to improvement in this respect. The business of the miner is essentially a practical one, and can only be acquired in the recesses of the mine, and amidst the busy operations carried on upon its surface. Though this obvious truth must be admitted to its full extent, it is impossible not to see that the results of science must, though unconsciously to the miner, be needed at every step. In the most costly, the most anxious, and at the same time the most precarious of all mining processes, the exploration of the ground for purposes of discovery and trial, geology may be made of the highest value: in understanding the nature and value of the heterogeneous mineral bodies presented to our view in underground works, chemistry and mineralogy are essential, and it is entirely upon the former science that the whole art of metallurgy is established. Again, we have seen that machinery

and mechanical contrivance are necessary at every step of the miner's progress, a circumstance which renders a knowledge of mechanics indispensable; and in pursuing the complicated operations of underground discovery, loss and error can only be avoided by the aid of geometry and subterranean surveying.

Thus then we may perceive that, in addition to practical knowledge in mining, there is a wide scope for the application of scientific knowledge also; in fact, it is continually in requisition, not merely in the general arrangements, but in the details also, and ought therefore to be possessed, to a certain extent, by the mining classes. Among those nations of Europe by which mining is most successfully cultivated, the value and necessity of scientific knowledge among miners have long been perceived, and ample provisions have been made for its attainment, as may be seen in the mining-schools of France and Germany. Although Great Britain possesses the richest and most productive mines in the world, it is remarkable that, till within the last thirty years, nothing was done in this country to provide the means of instruction for those who are designed for the profession of mining. Thus both the working miner and the mine agent had, in this country, no knowledge whatever of the principles on which the success of their operations depends, but proceeded entirely upon the practical skill acquired in the course of their experience.

Mining Schools.—When treating of the history of mining at the beginning of this article, the establishment of several institutions for the attainment of those acquirements which are needed in the professions of civil engineering and mining was noticed as forming the most recent event connected with the subject, and in course of time the benefits thus derived will no doubt be strikingly apparent. The mining-school of Cornwall formerly placed in operation by Sir Charles Lemon, might have supplied able miners well instructed in all that relates to the working of our tin, copper, and lead mines; while the university of Durham will, it is to be hoped, produce mining engineers whose qualifications will have a more especial reference to the working of coal and other minerals which occur in the stratified rocks of the north of England; and the School of Mines at Jermyn Street, will tend to systematise and diffuse the knowledge of the more general principles of mining. Thus by introducing a system of sound mining education, and by the continual progress of science, aided by the efforts which are now being made by government to supply desiderata which have long been required by the mining interest, we may hope still to maintain our mines in a flourishing condition, notwithstanding their depth, their heavy expenditure, and the increasing competition of other countries.

The total quantities of the metals raised from English mines, in 1858, was given by Mr. Hunt, as follows:—

Tin	6,920 tons.	value	£823,480
Copper	14,456 „	„	1,562,693
Lead	68,303 „	„	1,489,005
Silver	569,345 ounces.	„	156,569
Zinc	6,900 tons.	„	174,225
Iron	3,456,064 „	„	10,713,798
Total			£14,919,770

MINING, COAL. Although it would be impracticable to enter upon the various modifications of mining processes which are required in the working of all the varied natural depositaries of mineral wealth, the peculiarities of coal-mining are such as to require a brief notice, important and extensive as are the coal-mines of this country, and the arts and manufactures supported by them.

The nature and distribution of our carboniferous deposits have been already fully described in the article **COAL-FIELDS**, in **NAT. HIST. DIV.** In working mines of coal, or indeed of iron-stone or rock-salt, and other minerals which are found in beds, the object to be attained is the effectual opening and extraction of a tolerably uniform mass of small thickness, but of great horizontal extension. The process thus differs considerably from the working of mineral veins, where the object of research is fluctuating and irregular in its produce, and either vertical or highly inclined in its position. The thickness of beds of coal may be said generally to vary from three or four to eight or nine feet, although sometimes, when several seams come together without any intervening layers of rock, they may expand to twenty or thirty feet, of which we have an example in the “ten-yard coal” of Staffordshire. In every coal-field there are many seams of coal at greater or less intervals, one below another, of which as many as three or four are frequently worked in the same mine; and interstratified with the rock which divides them there are in many coal-fields extremely productive beds of ironstone, which are wrought at the same time, and in a similar manner with the coal.

The mode of working coal-mines will be most clearly understood by tracing the works from their commencement, in the same manner as in the former article. From the geological indication of coal and the known extension of its beds over very considerable areas, it is pretty certain to be found in the trials which are made for it, if carried on with proper judgment. The probable existence of beds of coal in depth having been ascertained, and perhaps the beds themselves discovered by boring, the first process is to sink a perpendicular shaft from the surface so as to intersect the various strata containing the

coal, and of course as many of the beds of coal as are considered to be worth working. The shaft is generally circular, and may vary according to circumstances from six or seven to eight or ten feet in diameter; the upper portion, as far down as the solid rock, is either bricked or walled, and where the ground is weak this casing may be continued throughout. On reaching the first workable seam of coal, the sinking of the pit is for a time suspended, and a broad straight passage termed a “bord” or “gate” is driven from it upon the seam of coal, in opposite directions. The breadth of the passage is usually twelve or fourteen feet, and it is formed the whole height of the seam of coal, so as to expose the stratum above, which is called the “roof,” and the one below, which is termed the “thill,” and its direction is always arranged so as to follow the cleavage of the coal which forms its sides, which thus present a clean uniform surface. When the bord or “mother-gate” has proceeded some distance on both sides of the pit, narrow passages, termed “headways,” are driven from it at regular intervals, and exactly at right angles; and when these have proceeded eight or ten yards, they are made to communicate with another bord, which is opened parallel to the first and on each side of it. It will be seen that by continuing this system of excavation the bed of coal will be entirely laid open and intersected by a series of broad parallel passages or bords of about eight yards apart, communicating with each other by narrower passages or “headways,” which cross them at right angles, and likewise traverse the whole extent of the mines; immense square or rectangular pillars of coal being left standing between the two. A coal-mine in this state is not in fact unlike a regularly-built town; the bords and headways may be compared to the principal streets and the narrower streets which cross them; while the pillars of coal may be said to resemble the intermediate masses of buildings.

The water encountered in the above operations is drawn to the surface by a powerful steam-engine erected on the shaft, which is so arranged as also to raise the coal and rubbish, for which purpose either “corves” or baskets are commonly employed. Supposing the above operations to have been successful as regards the prospects of the mine another shaft will now be commenced at some distance from the first, and when the communication between them has been effected, the one being made the downcast and the other the upcast, the air is conducted from the latter to the former through all the bords and workings, which it must traverse in succession in consequence of “stoppings” or doors which are fixed in various places to obstruct its progress and give a proper direction to the current passing to the upcast shaft. Till such communication can be formed, the first shaft may be divided by a “brattice” or partition, and be made to answer the purposes of both; some few coal-mines are indeed worked entirely in this manner, but the danger of explosion is considerable when the workings become extensive.

While the workings on the first seam of coal are thus going on, the shaft may be sunk to a second or third seam, where similar operations will be commenced, small underground pits or “staples” being sunk at intervals from the workings of the upper seam to those on the seam below, by which ventilation will be promoted. These operations, like those described in the former article, may be carried on indefinitely, and will thus in time form an extensive colliery. The regularity and uniformity of the working however are greatly modified by the occurrence of faults and other local accidents, and the pillars themselves are finally removed to such an extent as to cause subsidences of the roof and undulations of the floor, which present a most frightful appearance to the stranger.

The mode in which the pitman carries his excavation upon the coal is by cutting a narrow fissure in the seam on each side of the bord, and undermining the coal between, finally detaching the great cubical mass thus circumscribed by putting in two or three shots, which are simultaneously fired at the top of the seam. From 60 to 80 or 100 tons of coal may thus be brought down at once, when it is put into corves drawn along a tram-road to the shaft, and thence raised by a steam-engine to the surface, where it is often passed over gratings or “screens” in order to separate the small pulverised coal from the larger masses, which in coal countries are alone valuable.

In mines which are not endangered by explosive gases or “fire damp,” the coal-miner or “pitman” is guided in his operations by the usual subterranean light—a small candle stuck into a piece of moist clay; but where the fire-damp is apprehended the safety-lamp is used, which has long superseded the primitive contrivance of the steel-mill, the light of which was produced by the contact of a flint with the edge of a wheel kept in rapid motion. Notwithstanding the use of the Davy lamp, and the improvements which have taken place in ventilation, accidents from explosion are unfortunately still of frequent occurrence, although perhaps in most cases they may be traceable to some neglect or imprudence on the part of the men themselves. Attempts have recently been made to apply coal gas to the lighting of tin-mines and coal-mines, both in England and in Belgium; but hitherto without success.

The quantity of coal raised in Great Britain in 1858, was not less than 65,008,649 tons.

MINIUM. [**LEAD: Red Lead.**]

MINOR (Latin), *Less*, or *Lesser*, is a term used to distinguish the mode or key that takes a minor 3rd. It is also applied to all the diatonic intervals, but chiefly to the 3rd. The minor 3rd comprises a

tone and a semitone—A, c; the major 3rd is composed of two whole tones—C, E. [KEY; MODE.]

MINOTAUR, son of Pasiphaë, wife of Minos, by a bull. He lived on man's flesh, for which reason Minos put him in the labyrinth of Dædalus, feeding him with criminals, and afterwards with the youths and maidens sent from Athens. Theseus, by help of Ariadne, killed him, thereby delivering the Athenians from the obligation of sending their children to be eaten. Such is the mythological story. Its meaning is uncertain. It very likely belongs to that class of mythological tales which express a political fact, and the connection in which Theseus stands with the Minotaur adds probability to this theory, for the exploits of Theseus are generally such effects as would be produced in historical times by the course of events in the formation of a polity. Such at least are his exploits in and about Attica, and there appears no sound reason to exclude this from the number. It may then perhaps be assumed that under the slaying of the Minotaur is shadowed forth the abolition of certain obstacles existing in the way of free intercourse between Athens and Crete. But the descent of the Minotaur from Pasiphaë (Πασίφαη) probably a name of the moon, and the Bull, one of the zodiacal signs, may perhaps imply some astronomical fact connected with the recurrence of the tribute paid to Crete. The affection of Ariadne for Theseus, in mythological language, may be taken to mean a union of Cretan and Attic tribes. Various other interpretations of a more or less fanciful character have likewise been suggested. The monster either in his early adventures, enclosed in the labyrinth, and fighting with or subdued by Theseus, is frequently represented by Greek artists.

MINSTREL, from the French *menestrel*, and that, in all probability, from *Ministrellus*, a diminutive of the Latin *minister*, as a term applied to a class of persons who were to administer by their skill to the amusement of their patrons. "The minstrels," says Percy ('Reliques of Ancient Poetry'), "sang to the harp verses composed by themselves or others." They appear to have accompanied their songs with mimicry and action, and to have practised such various means of diverting as were most admired in those rude times, and supplied the want of more refined entertainment. These arts rendered them extremely popular and acceptable in England and all the neighbouring countries, where no high scene of festivity was considered complete that was not set off with the exercise of their talents; and where, so long as the spirit of chivalry subsisted, they were protected and caressed, because their songs tended to do honour to the ruling passion of the times and to encourage a martial spirit.

The minstrels seem to have been the genuine successors of the ancient bards, who, under different names, were admired and revered, from the earliest ages, among the people of Gaul, Britain, Ireland, and the north, and indeed by almost all the first inhabitants of Europe, whether of Celtic or of Gothic race; but by none more than by our own Teutonic ancestors, particularly by the Danish tribes. Among these they were distinguished by the name of Scalds, a word which denotes "smoothers and polishers of language."

This derivation of the minstrels from the Scalds and Gleemen of the north rests on fair historical testimony; and the reader will not fail to call to mind the incidents recorded of several Saxon and Danish princes, who assumed the disguise of Gleemen, and chanted to the harp when exploring a hostile camp.

The name of minstrel is, however, Norman. "It is well known," says Percy, "that on the Continent, whence our Norman nobles came, the bard who composed, the harper who played and sang, and even the dancer and mimic, were all considered as of one community, and were even all included under the common name of minstrels:" hence we may add their Latin names of *Mimi*, *Scurræ*, *Histriones*, *Joculatores*, &c. In France, however, the name of the class was *Trouverre*, *Trouveur* or *Troubadour*.

Joculator Regis is an officer holding no less than three villis in the return of the Domesday survey for Gloucestershire; and in the same survey, in Surrey, we have a *Joculatrix*. Wace, Gaimar, and our own historians William of Malmesbury and Huntingdon, all concur in the statement that a warrior-minstrel of the name of Taillefer rode before the conqueror's army previous to the battle of Hastings, flinging up and catching his sword in defiance, and singing the song of Roland.

To trace the existence of the minstrel profession minutely through the reigns immediately subsequent to the Conquest seems unnecessary. Rahere, the founder of St. Bartholomew's Priory in Smithfield, is recorded as the "*mimus Regis Henrici I.*"

Warton, in his 'History of English Poetry,' vol. ii., p. 105, has cited several instances of the high pay to minstrels:—"During many of the years of the reign of Henry VI.," he says, "particularly in the year 1430, at the annual feast of the fraternity of the Holy Cross at Abingdon, a town in Berkshire, twelve priests each receive fourpence for singing a dirge; and the same number of minstrels were rewarded each with two shillings and fourpence, besides diet and horse-meat. Some of these minstrels came only from Maydenhithe or Maidenhead, a town at no great distance, in the same county."

From the time of Edward IV., however, the real character of the original minstrel was becoming rapidly extinguished, and even the name seems to have been gradually appropriated to the musician only. At Queen Elizabeth's magnificent entertainment by Leicester, at

Kenilworth Castle, in 1575, it is true a personage was introduced to amuse the queen, in the attire of an ancient minstrel, who called himself "a squire minstrel of Middlesex;" but this was, no doubt, a part of the masquerade: it was the representation of a former day, not one of an existing profession. Laneham ('Princely Pleasures of Kenilworth,' Nichols's 'Progresses of Queen Eliz.,' vol. i.) says:—"After three lowlie cooursiez he cleered his vois with a hem and a reach, and spat out withal; wiped hiz lips with the hollo of his hand, for fyling his napkin, temper'd a string or too with hiz wreast, and, after a little warbling on his harp for a prelude, came foorth with a sollem song, warranted for stoory oout of king Arthurz acts."

Before Elizabeth closed her reign the degradation of minstrelsy was completed. By a statute in her 39th year, minstrels, together with jugglers, bear-wards, fencers, common players of interludes, tinkers, and pedlars, were at one sweep included among rogues, vagabonds, and sturdy beggars, and adjudged to be punished accordingly. Ritson quotes some satirical lines in allusion to this statute, written by Dr. Bull:—

"When Jesus went to Jairus' house,
Whose daughter was about to dye,
He turn'd the minstrels out of doors,
Among the rascal company:
Beggars they are with one consent,
And rogues by act of parliament."

This act put an end to the genuine old minstrelsy as a profession; and the modern definition of minstrel is no more than a "musician, a player upon some instrument."

MINT, the place where money is coined, from the Anglo-Saxon *mynet* (money or coin), and that in all probability adopted from the Latin *moneta*.

Of the manner in which the Britons conducted the coinage of their rude substitutes for money, few or no notices can now be recovered. The passage from Caesar, on which the supposition had been founded that the value of the pieces of metal were determined only by weight, has been proved by Mr. Hawkins ('Remarks on the Ancient British Coins,' in 'Monumenta Historica Britannica,' p. cii.) to have been altered in the 17th century. In all the principal manuscripts of the 'Commentaries,' the passage supports the conclusion that the Britons had brass and silver coins. Of the earlier coinage of the country a notice will be found under NUMISMATICS.

If the Romans actually coined money in Britain, of which, we presume, there can be no doubt, their mints were probably superintended by the same officers as were employed in other parts of their dominions; but no documents have yet been produced in proof of it; nor is anything known respecting the mints of the British kings after the departure of the Romans.

On the early Anglo-Saxon coins are found, in addition to the names of the kings, those of other persons also upon the same piece, who are with great probability conjectured to have been the moneyers; because on later Anglo-Saxon money the names of those officers frequently occur, with the addition of their title of office. From the circumstance of their names being inscribed on the coins, it is reasonable to conclude that they were responsible for the integrity of the money; and likewise that they were the principal officers of the mint. The silence also of the Anglo-Saxon laws and of Domesday Book as to other officers of the mint, whilst they so frequently mention the moneyers, strongly corroborates the opinion that they were the only persons employed in the Anglo-Saxon and early Anglo-Norman mints, except perhaps occasional labourers; but an officer called the reeve seems to have had some connection with the mint, or some jurisdiction over it. In the reign of Henry I. the money was so much debased as to call for exemplary punishment on the offenders, which is said to have been inflicted on moneyers only, without the least notice of any other officer. ('Sax. Chron.,' sub An. 1125.) This was also the case upon a similar occasion in the reign of Henry II. ('Chron. Joh. abb. S. Petri de Burgo,' Sparke, p. 78.)

After the Norman conquest the officers of the mint appear to have been, in some degree, under the authority of the court of Exchequer, as they were admitted to their respective offices in that court, and took the usual oath of office before the treasurer and barons.

Ruding observes that if the gerefa, or reeve, above mentioned was not the presiding officer of the Anglo-Saxon mints, he is unable to ascertain at what period it became necessary to place some permanent superintending authority in the mint to prevent any ill-practices of the moneyers; but he thinks it probable that such an officer was appointed between the 26 Henry II., when the moneyers alone were punished for the adulteration of the money, and the third year of Richard I., when Henry de Cornhill accounted for the profits of the cambium of all England, except Winchester. (Madox, 'Hist. Exch.,' vol. ii.)

In the Anglo-Saxon and the early Norman periods there were many mints beside the king's, and some were continued to a much later time. Barons and bishops struck money, especially in King Stephen's reign, and in two or three instances the privilege of coining was granted to greater monasteries. Wolsey's exercise of this franchise, both as bishop of Durham and archbishop of York, is well known: and there are coins of the archbishops of Canterbury, distinctly marked as such, at intervals from Jaenberht, consecrated in 793, to the close of

the reign of Henry VIII. Of the lay barons of Stephen's time, we have but one coin now extant, usually ascribed to Robert earl of Gloucester. Pegge's 'Dissertation on the Coins of the archbishops of Canterbury,' Noble's on those of the bishops of Durham, and more particularly Ruding's enumeration of the places where Mints and Exchanges have been fixed in Britain and its dependencies, will supply the reader with the amplest information upon this subject.

From a very early time the moneyers seem to have enjoyed exclusive privileges. In the 33 Henry II. the moneyers of York were expressly exempted from the payment of the "Donum," which was assessed upon the men of that city. (Madox, vol. i., p. 635.) In the 18 Henry III. the mayor, &c., of London were commanded not to infringe upon the liberties of the king's moneyers of London, by exacting from them tallages or other customs contrary to their privileges (Cl. 18 Henry III., m. 30); and before his 41st year those privileges appear to have been extended to the whole body of officers belonging to the mint; for at that time the bailiffs, &c., of Canterbury were ordered to appear in the Exchequer to receive judgment for having distrained upon the officers of that mint. (Madox, 'Hist. Exch.,' Ruding, 'Annals of the Coinage.')

The earliest grant of these privileges by charter was in the reign of Edward I., when the officers of the exchange and of the mint were (by the names of the keepers of the changes of the city of London and Canterbury, the labourers, or workers, money-makers, or coiners, and other ministers deputed or appointed unto those things which touch the office of the changes aforesaid) freed from all tallages, and were not to be put into any assizes, juries, or recognisance, and were to plead before the said keepers of the changes only, except in pleas appertaining unto freehold and the crown.

These privileges were granted to them so long as they should continue in the above-mentioned offices, and were confirmed by Edward II. in his second year, with this addition, that they were to be quit of all manner of aids and contributions, as well as tallages, and that if at any time they should, of their own proper will, grant any aid or contribution, such should be levied upon them by the keepers of the exchanges aforesaid, and that no other should intermeddle. The keepers themselves were in such case to be taxed by the barons of the Exchequer. Letters-patent to the same effect were issued by Edward III., Richard II., Edward IV., Henry VII., Henry VIII., Edward VI., and Philip and Mary. All these are referred to in the charter of incorporation which was granted by Elizabeth in the first year of her reign, but those of Edward I. and Edward II. alone are given at length.

In that year Queen Elizabeth granted a charter to the workers of the mint, by which important privileges were secured to them. Many of these privileges were enjoyed till a recent period, but were gradually restricted, and are now wholly abolished. In 1799, by the 39 Geo. III. c. 94, the salary of the master and worker of the royal mint was fixed at 3000*l.* a-year, in lieu of all fees, perquisites, and emoluments, which in cases of recoinage were declared to be "excessive;" but the fees were to be received as usual and paid into the Exchequer. In 1831, the act of 1 & 2 Wm. IV. cap. 10 reduced the salary to 2000*l.* a year. In 1837, the 7 Wm. IV. c. 9 enacted that all fees, allowances, or emoluments authorised by the indenture between the master of the mint and the king, should cease altogether from April 5th in that year; that from the same date no part of the seignorage on the coinage of silver or copper should be applied in any way to the expenditure of the mint, but should be paid into the exchequer; and that the treasury might authorise the master of the mint to purchase bullion for purposes of coinage, the means to be furnished from the consolidated fund, the money received for the coin to be repaid into the exchequer, and an account to be laid before parliament within ten days of the commencement of the session.

In 1848 the government appointed a commission to inquire into the working of the Mint system and to suggest remedies. The report presented by the commissioners showed that the system was extremely complicated; and that many of the officials, especially the refiner and smelter, and the moneyers, received inordinately large emoluments. These persons regarded themselves as a sort of close corporate body with vested rights; and it was with the utmost difficulty that the commissioners could obtain from them any details concerning their profits or receipts. The official routine at that time may shortly be described thus:—The master gave to the refiner and moneyers a certain weight of gold and silver, and the latter returned to him a *less* weight of coined money; the difference being their salary, profit, or reward for conducting the refining and coining operations. The master was, himself, always an adherent of the government for the time being; his was a political office, with a salary of 2000*l.* a year; and the holder interfered very little with the proceedings of the regular staff at the Mint. The commissioners recommended very extensive changes to be made. When the late Mr. Sheil was Master of the Mint, in 1850, the government requested him to draw up a plan of reform, based on the report of the commissioners, with such modifications as seemed to him desirable; he did so, entering minutely into the details of the subject. Mr. Sheil being soon afterwards appointed to the embassy at Florence, the government acted on one of the suggestions of the commission, by appointing a scientific person as Master of the Mint, instead of a mere political adherent; Sir John Herschel became master. He approved of the various proposed reforms; and an order in council in 1851 authorised

them to be made. It was a most difficult matter to effect a compromise with the assayers, refiners, moneyers, smelters, engravers, and others, owing to the enormous sums which they demanded for a relinquishment of their several privileges; but this was at length effected, and the new system was got into working order by the beginning of 1852. Professor Graham has since succeeded Sir John Herschel. All the officials at the Mint are now paid regular salaries, without any retention of the vicious system of fees and perquisites; and the master is empowered to contract for coining, to be conducted by persons not connected with the Mint, if he thinks the public advantage can be served by so doing. An arrangement was at the same time made, whereby Sir Anthony de Rothschild took a lease of the government refinery at the Mint for ten years; he is bound to refine all the gold and silver that the master may send to him, within a certain maximum and minimum, at a fixed price of 4*s.* per lb. for gold, and 6*d.* per lb. for silver; but he is permitted to refine other bullion also on his own account; while the master is permitted to employ other refiners in addition to Sir Anthony.

There are three matters which must be kept separate, in order to a due understanding of the coinage as a great national manufacture:—namely, the relations between the government, the Bank of England, and the Mint; the relations between the master and his subordinates; and the actual manufacturing operations. Of these three we shall treat in succession in a brief form.

The Mint is bound to convert into coin, at the public expense, any and all gold bullion that may be brought to it for that purpose, if quite or nearly of standard fineness. Practically, the Bank of England is almost the only customer to the Mint in this way, owing to certain facilities which that great establishment has for managing monetary affairs. The gold coins, sovereigns and half-sovereigns, are sent back to the Bank of England in exchange for the bullion received from thence. Sometimes the Bank comes into possession of gold coins of various dates, countries, and standards; these being troublesome to deal with, are converted into "sterling." Bags, containing about 700*l.* worth each, are taken to a refiner's in the city, and melted, each bagful into one bar. The bars are then sent to the Mint to be assayed, and in most cases to be coined into sovereigns and half-sovereigns. The loss by wear and tear, as well as the expense of coining, are borne by an annual vote of the House of Commons. Silver and copper are differently treated. The Mint officers purchase silver bullion, pure copper, and old silver and copper coins, in such quantities as are necessary for the purposes of trade, coin them into silver and copper pieces, and sell or exchange these for gold or notes to any applicants.

The second subject adverted to, namely, the relation existing between the master and his subordinates, or the organisation of the Mint under the new system, may thus be briefly described. The duties undertaken by the Mint are threefold—to receive, and convert into coin at the public expense, all gold bullion of nearly standard fineness, which may be sent thither for that purpose; to buy silver and copper, convert them into coin, and facilitate the exchange by the public of gold or notes for such coin; and to make all such coins for colonial use, and such medals for the public service, as the Treasury may require. To perform these duties there are several departments at the Mint—namely, a Mint office, for the receipt, custody, and delivery of bullion and coin; an assay department, for ascertaining the quality of coin and bullion; a melting establishment, for converting the bullion into bars of the proper standard and proportions for coinage; a coining establishment, for converting the bars into coins or medals; a die establishment, for providing or obtaining the stamps, dies, or engraved devices, to impress upon the coin; and a machinery department, for keeping in due order the various engines and machines employed. Under the old *régime*, the arrangements between all the persons employed were tiresomely minute and complicated; but at present the Mint bears more relation to an intelligible manufacturing establishment.

In ancient times extraordinary methods were resorted to in order to furnish the mint with workmen. Thus in the 31st Henry III., a writ was issued, authorising Reynier de Brussell to bring into England, from beyond the seas, persons skilled in the coinage and exchange of silver, to work in the kingdom at the king's charge. (Pat., 31 Hen. III., m. 3.) And in the 25th Edw. III., Henry de Brussell and John de Cicestra, masters of the mint, were appointed by letters-patent to choose and take as many goldsmiths, smiths, and other workmen in the city of London and other places, where it might seem expedient to them, as should be necessary for the works of the mint in the Tower of London; and to bring the said workmen to the said Tower, and to place them there to work at the wages allowed by the said masters. And any of them which should be rebellious in that case, to seize and arrest, and to detain in prison within the said Tower, and to keep in safe custody until the king should determine upon their punishment. These letters were directed to all sheriffs, &c., who were commanded to assist the said masters in carrying their provisions into execution. (Pat., 25 Edward III., p. 2, m. 13 dors.) This power to take workmen, &c., for the service of the mint was not discontinued in the reign of Elizabeth. ('Indent. with Lorison,' 14 Elizabeth, in 'Harl. MSS.,' Brit. Mus., 698.) The custom of placing the moneyer's name upon the coins prevailed, as already observed, at a very early period in this island; indeed we find it upon the money of Ecgberht, king of

Kent, which is the second in point of antiquity in the Anglo-Saxon series, and must be dated about the middle of the seventh century. It was usually stamped upon the reverse of the coin, but in some few instances it is found upon the obverse, whilst the name of the monarch is removed to the other side. The names of two moneyers sometimes occur upon the same coin. From the time of Aethelstan, with some few exceptions only, the name of the town was added, probably in conformity to his law that the money should be coined within some town. (Wilkins, 'Leg. Anglo-Sax.') The name of the moneyer is not found lower than the reign of Edward I., but that of the mint was not entirely disused in the last year of Queen Elizabeth.

We now come to the third subject—the actual manufacturing processes. The mode of coinage in early times, at least in this country, as far as it can now be traced, was rude and inartificial; the sole expedient employed being to fix one die firmly in a wooden block, and to hold the other in the hand as a puncheon; when, by striking the latter forcibly, and repeatedly, with a hammer, the impression required was at length worked up. This method appears to have been nearly coeval with the first invention of coined money; and it is a singular fact that no improvement of any importance was made in it, until the power of the screw was applied to coinage in the French mint about the middle of the 16th century. (Le Blanc, 'Traité Hist. de Monnoyes de France.')

The present mode of proceeding at the Mint may be briefly described as follows:—

When ingots of gold arrive at the Mint, they are carefully weighed, the weight registered, and a receipt given. Assay pieces are cut from them; and they are assayed, to ascertain exactly how much the gold is above or below standard, if at all. They then pass to the melting-house, where the melter weighs them, and gives a receipt for them. Each ingot is about 8 inches long, 3 inches wide, and 1 inch thick; if the gold be standard, the value is about 800*l.*; and to bring it to standard, an amount of alloy is added depending on the result of the assay. Six ingots, with the necessary alloy, are put into one crucible; and several such crucibles are placed in seven charcoal-heated furnaces. Numerous cast-iron moulds are arranged in a frame; the molten gold is poured into these; and when cold, each mould is opened, and a bar of gold taken out, 21 inches long, $1\frac{1}{2}$ inches broad, and 1 inch thick, if for sovereigns; but somewhat longer and narrower if for half-sovereigns. If for silver coinage, the ingots are 13 inches long, 5 inches wide, and 4 inches thick, valued at about 250*l.*; the weighing, assaying, melting, and casting into bars, are nearly the same as for gold, but requiring larger apparatus, on account of the greater weight of metal operated upon. The bars into which the silver is cast are 21 inches long, from $\frac{7}{8}$ to 2 inches wide, and from $\frac{3}{4}$ to 1 inch thick, according to the kind of coins to be made. The bars are then transferred to the rolling-mill. The machinery next brought into use is of a very powerful character, worked by steam-engines recently set up by Messrs. Hall. There are six pairs of rolling-cylinders, varying from 14 to 10 inches in diameter, all with hardened steel surfaces, and highly polished. Every bar is passed many times through the rollers, which are brought closer and closer to accommodate the reduced thickness. The bars, thus lengthened to 7 or 8 feet, are cut into five pieces each; then annealed in a furnace; then rolled again; and so on—until brought to the respective thicknesses for the different kinds of coin; or rather, slightly in excess of that thickness. All these operations are nearly the same in character for silver and for copper coins as for gold.

The fillets of gold are then transferred to the flattening-mill, where they are passed between rollers exquisitely adjusted, so as to make the fillet uniform in thickness in every part, and exactly thick enough for a sovereign or half-sovereign. Trial-blanks cut from each fillet must not vary in weight more than $\frac{1}{16}$ th of a grain, or the whole fillet is rejected. The cutting-out of a small number of trial-blanks is effected by a hand-punch; but the cutting-out of the blanks which are to form the coins themselves is the work of twelve powerful presses ranged in a circle. The fillets are fed into each press by boys; and stamps, worked by pneumatic power, speedily cut them up into blanks. Each machine cuts out as fast as a boy can feed it (about 60 per minute); and in busy times the whole twelve presses cut about 200,000 sovereign-blanks per day. The scrap or *scissel* is sent back to the melting-house. After another careful weighing and registering, the blanks are tied up in bags and sent to the weighing-room. Men used to be employed, under the name of *sizers*, to weigh each blank separately; but in 1855 twelve exquisite automatic weighing-machines were introduced, the invention of Captain (afterwards Colonel) Harness, the deputy master. Machines of somewhat similar character had been before invented by Mr. Cotton, to be used for sovereigns at the Bank; but those now adverted to are for blanks. The blanks are fed into each machine through a spout; a slide pushes each blank upon a delicate balance, where it remains exactly three seconds to poise itself; if correct in weight to $\frac{1}{10}$ th of a grain, another slider comes forward and pushes it over the edge into a "medium" or correct box; while the few, very few, which overpass this limit in either direction, are pushed into a "heavy" or "light" box, as the case may be. Under the sedulous care of Colonel Harness and Professor Graham, the rolling, drawing, and cutting-out are now so accurately performed that 98 or 99 blanks fall into the "medium" box out of every 100. All blanks for gold coins, and all for silver coins except those of very small denominations, are now tested by

these beautiful machines; these small coins are tested at so many to the ounce, and copper coins at so many to the pound—or, at least, the blanks for them. The weighed blanks are then passed to the marking-machines, which are eight in number; these, by a very peculiar movement, so roll the blanks as to make the peripheries perfectly circular, and to raise a slight projecting edge on each surface—not to produce a *milled* edge, but to facilitate the stamping. After this, the blanks are annealed by being exposed to a cherry-red heat for a few minutes; they are next cooled in water, pickled or blanched in dilute sulphuric acid, dried with heated beech-wood sawdust, and made up into *journeys*, or bags of definite weight, which in the case of sovereign-blanks amount to 15 lbs. troy, or 701 pieces.

The blanks are next coined or stamped. The coining-presses, eight in number, are very strong and massive, having to bear a great strain during the operations. Rouleaux or piles of blanks are supplied to a tube, from which they one by one fall upon the lower die, supported by an anvil; the upper die is brought down upon the blank by a peculiar combination of screw-power and pneumatic power, and a sovereign stamped on both sides falls out, milled, too, at the edge. An analogous process, varied only in details, is employed for other coins. If all the eight presses are fully in action, they will stamp 200,000 coins per day. After being once again weighed, the sovereigns are put up in bags of 701, and these in larger parcels of 5608. On the day after being stamped, the sovereigns are conveyed to a central office, where they are *pixed*, or officially tested. If medals instead of coins are being struck, the operations are lengthened by this circumstance—that, on account of the high relief of the device, every blank requires many blows and many annealings before it can receive the full effect of the impression.

The amount of coinage in each year varies, according to the fluctuations of internal and foreign trade. In some years it barely reaches 1,500,000*l.*, while in others it has exceeded 12,000,000*l.* During the last twenty years it has averaged something over 5,000,000*l.* annually.

From the money, when completely finished, two pieces are to be taken from every 15 lbs. weight of gold, and two, at least, from every 60 lbs. weight of silver, one for the private assay within the Mint, and the other for the trial of the Pix.

Preparations are now being made for changing the character of the English copper money. The coins are not only very heavy, but they are absurdly unequal. One-fifth of the whole quantity is on an average 60 years old; and the pence then coined are at the rate of 16 to the pound, whereas those of later date are mostly 24 to the pound. The copper coinage at present in circulation is supposed to be about 3500 tons, worth 380,000*l.* as mere copper, but 800,000*l.* as coins. It is now intended to replace the whole of these with bronze coins, consisting of 95 parts copper, 4 of tin, and 1 of zinc. They will be so much lighter than the coins now existing that the government expect a profit beyond all the minting expenses, while the public will probably be well satisfied with the change. A bronze penny or halfpenny will be a *token*, issued for more than its intrinsic value; but where the government keeps good faith, no harm will result. The decided satisfaction expressed in France at the new bronze coinage has influenced the English government in this matter. If, as is stated, there are to be 48 bronze pennies to the pound, the weight of each will be only one-third of that of the massive old "ring" pence of George III.'s reign, and one-half of that of the smaller pennies; and the coins will be useful for weighing, at 3 to the ounce. At the present time (July, 1860), Mr. Leonard Wyon is preparing the dies, and Messrs. Boulton and Watt the machinery, for this new bronze coinage. A partial adoption of the decimal system concurrently with this change has been strongly urged, but no such plan seems to be intended.

A few words will suffice relating to colonial and foreign mints. The Royal Mint, on Tower Hill, makes the coins for most of the colonies; but the colonists have a voice in determining the denominations and values of the coins. The Canadian legislature adopted the decimal system of coinage in 1856, and had entirely new moneys minted to carry out the change. There are twenty-cent, ten-cent, and five-cent pieces in silver, and one-cent pieces in bronze. The sizes and weights have been very ingeniously adjusted, so as to make the coins useful as weights and measures, as well as moneys: thus, the cent pieces are exactly one inch in diameter, and weigh exactly 100 to the pound avoirdupois; they pass current for exactly 100 to a United States dollar, and 24 to an English shilling. The Calcutta Mint, for the service of a vast population in India, has for many years been one of great magnitude; but in 1859 it underwent such augmentations as rendered it the most important in the world; it has at least double the coining power of the London Mint. There are also large mints at Bombay and Madras. Australia, after the discovery of gold in that country, wished to have a mint for coining. Each colony applied in 1851. The government expressed willingness, under proper conditions for security, the colonies to pay the whole expense. The Master of the Mint prepared an estimate, showing that 10,000*l.* would be required for a building and machinery sufficient to coin 5,000,000 pieces annually, and that a larger outlay would ensure a yet larger ratio of increase in productive power. New South Wales, accepting the terms, transmitted 10,000*l.* in 1852 for the commencement of operations. Machinery was sent out in 1854, and the Sydney Mint commenced work in 1855; it coined about 450,000 ozs. of gold into

sovereigns and half-sovereigns in a year and a half, and more powerful machinery has since been sent out. In California there is a mint with great producing power, which has undergone gradual enlargement to adapt it to the wants of the gold-diggers and dealers of that country. The United States government has had experimental pieces minted in a mixed metal of copper and nickel; but they are very inferior in appearance to bronze. In France, the coinage is not managed by the government, but by a peculiar company, who are paid by the state at the rate of 1½ francs for coining 1 kilogramme of silver money, and 6 francs for 1 kilogramme of gold, the proportion between the number of large coins and that of small being matter of stipulation. In 1857 the French withdrew their copper coins, and replaced them with lighter and better stamped coins in bronze, realising a very considerable profit by the change, on account of the much smaller quantity and value of metal in the new coins than the old.

MINUET (*menuet*, Fr.), a graceful slow dance, which, according to Brossard, had its origin in Poitou, and, we conjecture, first made its appearance either in the middle or towards the end of the 17th century, for the term is not found in Mersenne, but is met with in the operas of Lully. *Ménage* derives the word from *menu*, "little," the paces of the minuet being small.

The minuet, as a dance, consists of two strains or parts, of eight bars each, in three-crotchet time, and both are repeated; but as it seems to have been introduced together with hoops and hair-powder, so it passed away with them, and has not revived with their revival: except now and then on the stage, it is only seen in dancing schools. As an exclusively musical movement, in symphonies, quartets, &c., each strain of the minuet generally comprises sixteen bars, both strains being repeated; and it is followed by a second, called the trio; after which the minuet is played once more, straight through. But composers are not very strict as to its length, or to that of its supplement the trio. For the latter kind of minuet we are indebted to Germany: its time is always quick—*allegro*; and when repeated after the trio, the movement is rather accelerated.

MINUTE. [ANGLE; SEXAGESIMALS; TIME.]

MIRACLES. A man may acquire his knowledge of any event in either of two ways; by his own observation, or by information from others. The knowledge of an event which a man obtains from his own observation is generally, to him, the highest degree of evidence and the surest ground of belief; but not therefore the surest ground of a true opinion. The knowledge of an event which a man derives by information from others is not, to him, so high a degree of evidence as that which he obtains from his own observation; but it does not therefore follow that it is not so sure a ground of true opinion. All the knowledge which a man derives from his own observation may be called experience: all that he derives from the observation of others may, for the sake of distinction, be called evidence; it is the experience of others communicated to him, either orally or by writing.

Every event which has taken place, or is said to have taken place, may be the subject of evidence. A man who has witnessed an event himself entertains no doubt of its reality, unless he has some suspicion that a fraud was practised, or that for some reason or other the event of which he was a witness was not such an event as it appeared to him to be. An eye-witness therefore of an event has nothing to guard against, so far as concerns his own conviction, but deception by others, or mistake or misapprehension on his own part. When a man derives his knowledge of an event from the information of others, there is, in addition to the causes of error which may exist where he is an eye-witness, the further cause of error which may arise from the witness whose evidence he receives being interested in deceiving him, or being, from whatever cause, disposed to deceive him. There is no supposable event which may not be the subject of evidence; and when all reason for supposing deception, mistake, or intention on the part of the witness to deceive, is removed, there is no event which, when witnessed, does not thereby acquire some degree of probability. It must be admitted that the ascertaining that there is neither deception, mistake, nor intention to deceive, is generally the main matter in estimating the value of evidence; but the estimating the value of the evidence in any given case is a different thing from determining what may be the subject of evidence, which is the matter that we are here considering.

Man is so constituted, that any event alleged to have taken place is at once placed by the mind either among events which are common or among events which are uncommon. In the former case, before any evidence is furnished as to the fact, there is a disposition to believe that it is true; and even the soundest judge of human events, though he will believe no alleged event without sufficient evidence, readily acquiesces in the probability of an alleged event of a common kind being a true event. In the case of an uncommon event, the matter is different; most persons are indisposed to consider it probable that the uncommon event has actually taken place, and many persons at once assume its impossibility, or at least assume that it has not taken place. But there is no rational ground either for admitting the truth of a common event without sufficient evidence, or for refusing assent to an uncommon event supported by sufficient evidence. An event the most common in the course of human life, an event the probability and possibility of which no man will deny, requires as much evidence in order to be proved as any event the most uncommon or any kind of

thing or event that has never been heard of before. In both cases, the testimony of one eye-witness at least is required; and supposing the absence of mendacity in the witness and of all reason for supposing him to be deceived, the uncommon event is proved as much as the common event. How much and what will be necessary in either case to show the absence of mendacity or of deception, is a question that concerns the estimation of the value of the evidence in any given case, and cannot be determined generally.

Thus, it appears that an event alleged to have taken place may either be one of a kind that is consistent with a person's experience, or it may be consistent with it. But the evidence in support of an event of either description may be precisely the same in degree and kind; it may be the evidence of persons of integrity unimpeached, of judgment approved, and of observation and acuteness unquestioned.

In the two cases supposed, the evidence is precisely the same: the only difference is in the mental state of the person to whom it is addressed. All intention or disposition to deceive, on the part of the witnesses, is by the supposition out of the way, and therefore the case is reduced to that of the receiver of the evidence being an eye-witness, and if he believes the witnesses to have as much penetration and judgment as himself, their evidence is as good to him as his own experience would have been; and if he thinks the witnesses have more penetration and judgment than himself, it is better. There is then no reason why a man should not, under the circumstances supposed, believe an event which is inconsistent with his own experience, as well as one that is consistent with it.

The true cause of all the dispute about the reality of events called miraculous is this:—the estimation of the evidence in the particular instance or instances, has been confounded with the question of evidence generally. As a matter of evidence, any fact may be alleged as the fact to be proved, and the possibility of a proof equal in value to the proof derivable from a man's own observation cannot be denied. But whether any alleged fact has been proved or not, is quite a different question. It is not here said that any supposable fact or event may, by possibility, be supported by evidence as strong as that arising from a man being an eye-witness.

The assertion that any alleged event is inconsistent with experience, may mean either the experience of the objector, or the evidence (that is, the experience) of others; or it may mean both. Taken in its widest acceptation, the assertion cannot be properly made of any fact or event alleged to have taken place; for by the supposition, the event is consistent with the experience of the person who bears evidence to it. If a fact or an event should be told to a person, of which there was no similar event on record, it might be said that experience did not show any similar event; but though this might be a very good reason for examining the evidence most strictly, it is no reason at all against evidence in support of it which is free from all the objections above enumerated.

But it may be said, what does this lead to? It leads to this,—to the admission that any alleged fact or event is a possibility; and it leads to the proper examination of the evidence by which it is supported. Suppose the event to be a shower of stones recorded in Livy. The investigation is relieved of one difficulty by the fact of showers of stones being attested by evidence in modern times much more satisfactory than that of Livy. A man may therefore commence such inquiry by admitting that the particular circumstance recorded by Livy may have taken place; though, if he had not satisfactory evidence of such a kind of events having taken place before, he could not commence his inquiry by making such admission; for the admission that such an event might have taken place could only be made when the event was proved to have taken place, and would then be useless. Further; prior to receiving any evidence, we cannot say that the event is one that could not have taken place. Whether a shower of stones, as recorded by Livy, did fall or not, depends for proof exactly on the same principles as other events recorded by him.

Now many of the facts or events which are called miracles are of the kind which may be considered as unlike any other events on record; the fact, for example, of Jesus raising Lazarus from the dead, which we will suppose, for the present purpose, to be the first event of the kind on record. With reference to an event of this kind, Hume remarks, "In order to increase the probability against the testimony of witnesses, let us suppose that the fact which they affirm, instead of being only marvellous, is really miraculous; and suppose also that the testimony, considered apart, and in itself, amounts to an entire proof; in that case, there is proof against proof, of which the strongest must prevail, but still with a diminution of its force, in proportion to that of its antagonist." The opposing proof here referred to is what Hume calls experience, a word which he has used in his Essay in a very loose sense. From what has been said in this article, it will be perceived that the view which the writer takes of evidence is altogether different from that of Hume. If the "testimony, considered apart and in itself, amounts to an entire proof," the thing or event is proved, whether it be one kind of thing or another; and this conclusion is logically contained in Hume's words. It is however clear that Hume did not mean to say that which his words do mean; for he urges against this, which would be entire proof if the thing were not miraculous, the objection that it is miraculous; and this is the whole of the matter that his Essay in effect contains, which, as it has been well remarked,

"confounds the principle of belief with the subject-matter to which it is to be applied." (Starkie, 'On Evidence,' i., p. 473, note.)* This is the case in the first part of Hume's 'Essay on Miracles;' the second part merely professes to show that no miraculous events have ever been established on so full evidence as may amount to entire proof.

Every person understands what is meant by the laws of nature. The material world and the world of thought are subjected to certain general laws, or, to speak more accurately, the phenomena succeed one another in a certain order, which, as far as evidence extends backward, has been generally unaltered. We say, generally, for deviations from this order are alleged to have occurred at various times and in various places. Now deviations from those laws are supposed to present, and indeed do present, events which stagger the belief of many persons, and which are regarded by others as totally untrue. Some have gone so far as to say that such events are impossible; thereby destroying the very ground of all evidence, for we can never determine beforehand the truth or falsehood of the matter offered to be proved; unless indeed the thing asserted and proposed to be proved should be a general proposition, and a man should be able by his own experience to contradict it in one or more particular instances: in such case, a man might beforehand deny the thing proposed to be proved. This is in fact Tillotson's argument against the real presence, which Hume "flattered himself" was of "a like nature" with the argument that he "had discovered."

Hume's definition of a miracle, at least the first part of it, appears unobjectionable: it is defined by him to be "a transgression of a law of nature by a particular volition of the Deity, or by the interposition of some invisible agent."

The true notion of a miraculous event then is an event that was inconsistent with the course of nature, as known at the time when the event is alleged to have taken place, and would be inconsistent with it if it were to take place now; and further, it must be such an event as by the supposition is inconsistent with and cannot take place by virtue of the laws of nature as established. If it is an event that happens by virtue of what is called a law of nature, known or unknown, it is not a miracle as the term is properly understood.

If the raising of Lazarus from the dead was an event which took place by virtue of a pre-established law or course of events, in which this one event, to us an apparent exception, was in fact a necessary consequence of this pre-established law or course of events, such event is not a miracle, nor such an event as is generally understood by the word miracle. Those men who would bring miracles within what are called the laws of nature, mistake the question. If the event of the raising of Lazarus from the dead, and all the attendant circumstances, took place in the course of things, agreeably to a general law unknown to us, such an event is as much an event consistent with what are called the laws of nature, as the event of any man's death; but in that case, it is not the kind of event which the New Testament presents to us. Whether however it is the one kind of event or the other, matters not as to the evidence of it, which is in no way concerned about the kind or quality of the event.

To take then the case of a man being raised from the dead; can the evidence of such a fact amount to proof? It can amount to proof as strong as that which a man would derive from being an eye-witness of such an event, and having every opportunity of examining it. Whether, in a given instance, the proof is so strong as this, must be ascertained by weighing the evidence, which is quite a different matter from the possibility of such an event being proved, which is all that is here insisted on. Whether the proof, when made as strong as we have supposed, will convince a man, is no longer a matter that in any way belongs to the general question of evidence. The judgment that a man will form on the report of others must be left to himself. As a man must always decide for himself whether he will trust his own senses, so he must also decide whether he can believe that which a credible witness says he has seen.

Other views of the nature of miracles, of their antecedent probability, historical character, and what is called 'evidential' value, differing more or less from what is set forth above, and, in their sceptical or critical point of view, from that of Hume, have, during the last few years, been repeatedly put forth and answered with great learning and logical acumen on the Continent (especially in Germany) and in our own country. The nature and extent of the controversy would however render it impracticable, even if it were desirable, to enter into it here, where all that has been attempted is to show the principle involved as a question of evidence and antecedent probability. The writings of Paulus, Rosenmüller, Wegscheider, and De Wette in German, and of Theodore Parker, F. Newman, &c., in English, will show the various phases of the recent sceptical and rationalistic reasonings against the credibility of miracles, whilst those of Archbishop Whately, Deans Lyell, and Trench, and Mr. Mansell will supply the arguments by which their objections have been met by what are regarded as the most orthodox authorities. With these may perhaps be compared the views of writers like Neander, Professor Jowett, and B. Powell.

MIRAGE [REFLECTION AND REFRACTION, ATMOSPHERIC, EXTRAORDINARY.]

* It may not be improper to add, that the writer by no means assents to all the arguments contained in the note referred to.

MIRROR. [SPECULUM.]

MISDEMEANOR is a term applied in the law of England to crimes and offences, whether of commission or of omission, less than felony. [FELONY.]

At common law, persons convicted upon an indictment [INDICTMENT] for a misdemeanor are punishable by such fine, or by such term of imprisonment short of imprisonment for life, or by such amount both of fine and imprisonment, as the court before which the offenders are convicted, in its discretion awards. By several statutes special modes of punishment are provided for some particular misdemeanors. But it frequently happens that even in creating new misdemeanors, the legislature affixes no particular punishment. In such cases, the newly constituted offence is punishable as a misdemeanor at common law. Generally, wherever a statute prohibits an act, as a matter of public grievance, or commands an act, as a matter of public convenience, all things done or omitted contrary to the prohibition or command are punishable as misdemeanors at common law; it being a common-law offence to disobey a statute, even though the act or omission be not attributable to a corrupt motive. Where a statute, in respect of an offence which was a misdemeanor at common law, provides a mode of proceeding different from that of the ordinary course by indictment, either the extraordinary or the ordinary mode may be adopted. Thus if a statute give authority to the court of quarter-sessions to make an order respecting some particular matter, and prescribes a particular remedy in case of disobedience, a party disobeying an order made in pursuance of the statute may be proceeded against either in the mode prescribed by the statute or by indictment. He would be guilty of a misdemeanor at common-law, both as having disobeyed a public statute, and as having disobeyed an order made by a court having authority to make such order. Where however a statute has made a matter a felony which before was a misdemeanor only, the offender cannot be indicted for the misdemeanor, as the minor or lower offence is said to be merged, that is drowned or absorbed, in the higher [MISPRISION]; but the statute 14 and 15 Vict., c. 100, s. 12, provides that if on a trial for misdemeanor, the facts given in evidence amount in law to felony, the accused is not by reason thereof to be entitled to acquittal; and no person tried for misdemeanor is liable to be afterwards prosecuted for felony on the same facts, unless the court discharges the jury from giving a verdict, and directs an indictment for felony. Where a statute creates a new offence, by making unlawful that which was lawful before, and appoints a summary mode of proceeding, the specific statutory course must be pursued, and an indictment will not lie. An act done in contravention of a statute which extends only to private persons, or relates to disputes of a private nature, cannot be made the subject of an indictment; for no injuries of a mere private nature not in any degree concerning the king, and not accompanied by a breach of the peace, can be made the subject of a criminal prosecution. Nor will an indictment lie for an infraction of the bye-law of a corporation. But under some circumstances an indictment will lie for a personal injury, where the act or omission amounts to a violation of duties incumbent on the party as a member of civil society, as in the case of a parent wilfully omitting to supply proper food to an infant unable to provide for itself. Where a child is put out apprentice by an order of magistrates, the master, if he refuse to provide for the child, may be indicted for disobedience of such order. Any act of wilful negligence, whereby human life is endangered, is a misdemeanor; as to put on board a ship a package containing gunpowder, oil of vitriol (sulphuric acid), or other dangerous articles without giving notice of the contents of the package, so as to enable the master of the vessel to use proper precautions in stowing it. Every act done for the purpose of committing either a felony or a misdemeanor, is itself a misdemeanor. By the 14 and 15 Vict., c. 100, s. 9, a person indicted for any misdemeanor may be found guilty of an attempt, and punished accordingly.

As to the former and present course of proceeding upon indictments for misdemeanors, see TRAVERSE.

Where a peer or a commoner is impeached by the House of Commons for a misdemeanor, the lords spiritual as well as the lords temporal are judges. The judgment is pronounced by the lord chancellor, and it is binding though the king dissent from such judgment; whereas in capital cases the royal assent is necessary, and the judgment is pronounced by the lord-high-steward. [STEWART.]

MISPRISION (from *mesprendre*, which means sometimes to deal improperly with, sometimes to treat with contempt), is a term used in English law in different senses.

I. In the sense of criminal nonfeasance, or neglect to perform important public duties, the term is applied to concealment of treason or felony. Misprision of treason consists in a party's withholding his knowledge of a treason committed, or about to be committed, or in omitting to give information respecting it within a reasonable time to some public authority. If the concealment or omission to reveal the treason be accompanied by express assent to the treasonable act or purpose, or by any circumstances from which a tacit assent will be implied, the party is guilty of high treason, as well as of misprision of treason; and the crown may prosecute either for the higher or the lower offence. Misprision of treason is a misdemeanor [MISDEMEANOR], punishable by imprisonment for life and the forfeiture of the personal

property of the offender absolutely, and of the rents and profits of his real property for life.

Misprision of felony is a similar concealment in respect of felonies, and it is punishable by fine and imprisonment. In some, if not in all cases of felony, the party may be proceeded against for the minor offence, or misdemeanor, although a felony has actually been committed by him.

The concealment of treasure-trove [TREASURE-TROVE] is another species of criminal neglect, which constitutes a misprision punishable by fine and imprisonment.

II. Misprision by malfeasance, (by doing something which ought not to be done,) is the commission of such misdemeanors as are construed to involve a contempt of the royal authority or prerogative. Maladministration in high offices of public trust, though indictable as a misprision, is commonly, on account of its importance, made the subject of parliamentary impeachment.

It is a contempt of the prerogative to refuse to assist the king when called upon, either in his councils by advice, or in his wars by personal service within the realm in cases of invasion or rebellion; to refuse to join the posse comitatus, or power of the county, when duly required by the sheriff or justices; to accept a pension from a foreign potentate without the consent of the king; to go abroad when forbidden so to do either by writ of *ne exeat regno*, or by a general proclamation, or to neglect to return from abroad when commanded by the king's letters; to disobey an Act of Parliament where no particular penalty is enacted; to speak or write against the king's person or government, or do anything tending to lessen him in the estimation of his subjects; to weaken his government, or to raise jealousies between him and his people; to deny the king's title to the crown in common unadvised speech [PRÆMUNIRE]; to use threatening or reproachful words to a judge in court; to assault or threaten the adverse party in a suit, or his counsel or attorney, or a juror for his verdict, or a jailor or other officer for exceeding his duty; to commit an affray near the courts of Westminster Hall, or at the assizes, but out of the view of the judges; to dissuade a witness from giving his evidence; to advise a person to stand mute; to disclose an examination before the privy-council or a grand-jury. All these are positive misprisings or contempts, punishable by fine and imprisonment. Maliciously striking in the palace in which the king resides, whereby blood is drawn, is punishable by fine, forfeiture, imprisonment, and formerly also by loss of the offender's right hand. Rescuing a person from the custody of one of the superior courts of justice, in Westminster Hall, or at the assizes, is punishable by imprisonment for life, forfeiture of personal property, and forfeiture of the rents and profits of real property during life. A stroke or blow given in any of these courts, whether blood be drawn or not, or an assault upon a judge whilst he is sitting in court, by drawing a weapon, though no blow be struck, subjects a person to the same penalties as those last mentioned, and formerly also to the additional punishment of loss of the right hand.

The misprision which is stated above to be included in the actual commission of treason or felony, may be referred to this second division, as it consists in malfeasance rather than in non-feasance. (Blackst. 'Com.' by Kerr, v. iv., pp. 119-123.)

III. The term misprision is also applied to careless but involuntary mistakes, or, as they would now be called, clerical errors, particularly those committed by public officers in entering the proceedings in a cause or in a judicial proceeding upon the rolls or records of the court; though it is also applied to misrecitals and mistakes in deeds, &c. (Roll, 'Abr.,' Grant.)

MISSAL (from the Latin *missa*), the book or ritual containing the several masses to be used on particular days or feasts.

The Roman missal was originally compiled by Pope Gelasius, and afterwards reduced into better order by Gregory the Great, who called it the Book of Sacraments. The 'Missale Romanum, ex decreto Concilii Tridentini restitutum,' is that at present in use. We have an edition before us, printed at Rome, in folio, 1826.

Anciently, each diocese, and each order of Religious, where they chose, had their particular Missal, accommodated to the festivals of the province or order. They were consequently extremely numerous. The Missals of the 13th, 14th, and 15th centuries, written previous to the discovery of the art of printing, present us, in many instances, with the finest specimens of illumination now preserved in our libraries, and command enormously high prices.

MISSIONS. The 15th verse of the 16th chapter of the gospel by Mark is the great scriptural authority for missions. In the 6th century (590-604) Pope Gregory the Great sent missionaries to Britain, to convert the people to the Christian faith. Similar means were adopted in other countries, until, about the close of the 10th century, when the Christian religion had become the prevailing faith throughout Europe. Other fields for missionary exertion were then sought. Attempts were made to propagate Christianity in Tartary and China; and the Portuguese, who visited Abyssinia about 1490, endeavoured to bring over the Christians of that country to the Catholic faith. The history of this mission may be seen in Mosheim's 'Ecclesiastical History.'

With the earliest maritime discoveries of the Portuguese the desire for the conversion of heathen people was excited with renewed zeal, and may even be said to have been instrumental in stimulating the passion for maritime expeditions. About 1430, Pope Martin V. granted

plenary indulgence to the Portuguese who conquered pagan and infidel countries. Columbus himself was strongly urged to discovery by the desire of propagating the Roman Catholic religion.

Modern missions may be said to have commenced at the same period with these discoveries, in which the popes took great interest. On the return of Columbus to Spain from his first voyage, the results were formally announced to Pope Alexander VI.

The work of converting heathen people was at first undertaken in a barbarous spirit. The commanders of the expeditions which Don Henry of Portugal sent out in the 15th century had "orders to convert the natives of the coast of Africa to Christianity;" and nominal conversions were often effected by the sword.

In 1484, Diego Cam brought four natives of Africa to the court of Portugal; they were sent back with presents and a message to their sovereign, desiring him to embrace Christianity. The natives whom Columbus brought to Spain were baptised, the king and the prince his son acting as sponsors. In his second voyage to the new world, Columbus was accompanied by priests with church vessels and ornaments, and they received orders to bring the natives within the pale of the church by "fair means." But fair means were not always adhered to. The natives were baptised by force, and without instruction, and many facts might be adduced to show that at this period true religion made little or no progress in newly discovered countries; and yet during the 16th century not a fleet sailed for India or America without its missionaries.

The stream of missionary enterprise was at length directed and regulated by different religious orders and distinct institutions. One of the objects of the Society of Jesuits, established in 1540, was the extension of the Roman Catholic faith, and the Jesuits soon became the most active and energetic missionaries in heathen countries. Their activity roused the zeal of the Franciscans, Dominicans, and other orders, and early in the 17th century institutions were founded with a view of rendering the labours of missionaries more effective by a preparatory course of training. In 1622, Pope Gregory XV. founded at Rome the 'College de Propaganda Fide,' which was soon richly endowed. Pope Urban VIII. was one of its principal benefactors. This college consisted of 13 cardinals, 2 priests, 1 monk, and a secretary. It sent out large numbers of missionaries to aid the propagation of the Catholic faith in all parts of the world; published books to facilitate the study of languages; distributed works of piety among various nations in their own language; and maintained in various institutions young men intended for foreign missions. To the above institution was added the "College or Seminary for the Propagation of the Faith," founded by Pope Urban VIII. in 1627, which became the central institution in which missionaries were prepared. This establishment is yet in active operation. Numerous institutions of a similar character were soon after founded in France. The "Congregation of Priests of the Foreign Missions" was instituted by royal authority, and about the same time the "Parisian Seminary for Foreign Missions" was established by an association of bishops and other ecclesiastics, for the education of foreign missionaries. The "Congregation of the Holy Sacrament" also a French establishment, was another of these institutions. These establishments were under the authority of the "De Propaganda" of Rome. Henry III. of France took considerable interest in foreign missions, and Henry IV. and Louis XIII. assigned funds for their support. Private associations were also formed in France, in the time of Richelieu, for sending missionaries to Canada, which were joined by many persons of rank and distinction. The Jesuits first visited Canada in 1608. In 1700, at the desire of Louis XIV., they endeavoured to propagate Christianity among the natives on the banks of the Mississippi. Towards the close of the 17th century there were not fewer than eighty seminaries in different parts of Europe which prepared and sent out missionaries. The Jesuits, Dominicans, Franciscans, and Capuchins were the most active in these undertakings, which were conducted on a large scale and with a regularity and combination of means altogether superior to the efforts made immediately after the discovery of America and of the path to India round the Cape of Good Hope.

India, Japan, and China were the principal fields of exertion. The exertions and success of Xavier in Japan and the East Indies will be found in the notice of him in the Biog. Div. China was also for a long time a scene of successful missionary exertion under the direction of the Jesuits. Father Roger, a missionary of this order, first preached the gospel in China in 1581. Matthew Ricci, an Italian Jesuit, was the first missionary who obtained an introduction to the court, and is justly regarded as the founder of the Chinese mission. Ricci proceeded to China in 1583, but he was not introduced to the emperor until 1601, when he presented to him a picture of Christ and another of the Virgin, and obtained permission to preach. Individuals were chosen for this mission on account of their scientific acquirements, and it was Ricci's mathematical attainments which rendered him acceptable to the emperor and the court. Adam Schaal, another of the missionaries, was employed to reform the Chinese calendar and their system of astronomy. Shortly afterwards two handsome churches were erected at Pekin with the permission and under the protection of the emperor. Under these favourable circumstances Christianity made considerable progress. But after several vicissitudes of favour and disgrace, the missionaries were in 1717 accused of seditious designs, and the emperor

confirmed a decree prohibiting the building of churches, and Europeans were in future only allowed to remain in China on condition of their promising never to return to Europe. In 1723 the throne was filled by an emperor who at first was rather favourably disposed towards the missionaries; but he afterwards issued an edict under which they were driven from the churches and only tolerated at Peking and Canton. Duhalde says that above 300 churches and more than 300,000 Christian converts were deprived of religious instruction by this act. Several families of rank were degraded or exiled by the emperor on account of professing Christianity. In 1732 the missionaries, 30 in number, were banished to Macao, having from motives of conscience disobeyed the edict which forbade the propagation of the Christian religion. Converts were at this period kept together by native catechists, and a few of the missionaries remained in China in concealment or re-entered the country by stealth. The mission is still carried on, in spite of the occasional attempts of the Chinese to put it down; the mission of Father Huc and his companions is the most recent, and the missionaries were expelled. There are still believed to be many Christian congregations served by native priests, but the numbers stated are by no means to be depended on, and the congregations are always liable to persecution.

In the 17th century the Jesuits sent many missionaries to the East Indies, to Tonquin, Bengal, Madura, the coast of Coromandel, and to Surat, with but moderate success. Of their efforts in South America, a notice will be found under PARAGUAY, in the GEOG. DIV.

In 1700 the three orders of Capuchins, Jesuits, and Carmelites were the most active missionaries. The Capuchins had 25 missions in Turkey, and missionary stations were established in Persia, Georgia, and Africa. The Jesuits had ten missions in Turkey, and the Carmelites three. Many of these missionaries had acquired a knowledge of medicine, and obtained access to families as physicians. In 1717 the Jesuits supported missions in the islands and continent of America, in Greece, Asia Minor, and the Archipelago, and in Egypt, Syria, and Persia, besides those in India. Louis XIV. made grants of land to the missionaries in Canada, and to them we are indebted for some of the earliest descriptions of North America.

In 1822 the cause of missions was revived in France by the Institution for the Propagation of the Faith, which has committees at Paris and Lyon. Several popes have granted to its members certain indulgences. The 'Annals of the Propagation of the Faith' are published by the society. The funds are placed at the disposal of the Seminary for Foreign Missions, and the superiors of the Lazarite Missions and the Jesuit Missions. There is no part of the world in which Catholic missionaries are not supported.

The first Protestant mission of which we have any notice was founded by the church of Geneva, which sent missionaries to America in 1556; but it is believed to have existed only a short time. Early in the 17th century the Dutch, who had taken Ceylon from the Portuguese, admitted the natives to employments under their government only on condition of subscribing to the Helvetic Confession, and becoming members of the Reformed church. Large numbers made a profession of Christianity, but comparatively few were real converts; and there was a consequent relapse when the coercion was removed by the cession of the island to Great Britain. In Java, Formosa, and Amboyna, the Dutch made attempts to gain converts. Translations from the Scriptures were made in the Cingalese and Malay languages.

It was some time after the English had begun to form settlements in North America before attention was directed to the religious condition of the natives. In 1644 a petition was presented to parliament from a minister of the Church of England, supported by many English and Scotch divines, which urged the duty of attempting to convert the natives of America to Christianity. Soon afterwards an ordinance of the Lords and Commons appointed the Earl of Warwick governor of the islands and plantations of North America; and a committee was appointed to assist him in several matters, "but chiefly for the advancement of the true Protestant religion, and for the spreading of the gospel of Christ among those that yet remain there in great and miserable blindness and ignorance."

In 1646 the General Court of Massachusetts passed the first act "for encouraging the propagation of the gospel amongst the Indians." In 1649 an incorporated body was established with the authority of parliament, under the title of the "President and Society for the Propagation of the Gospel in New England." In 1661 Charles II. renewed the Society's charter, on the ground that it was now fit to lay a foundation for "educating, clothing, civilising, and instructing the poor natives." The design of the Society was to support and maintain ministers and schoolmasters to instruct the natives in the English language, and to teach them useful trades. Eliot, called the "apostle of the Indians," and Mayhew, had already laboured for several years in the conversion of the native tribes of New England. In a narrative of their exertions, published in 1653, and dedicated to Cromwell, an account is given of the conversion of several chiefs. In "A Later and Further Account," published in 1655, Eliot states that a great desire for baptism had arisen amongst the Indians; but never was there a missionary so conscientiously scrupulous as to trusting to professions of this kind. He told the Indians "how necessary it was that they should first be civilised by being brought from their scattered and wild

ARTS AND SCI. DIV. VOL. V.

course of life;" and he began the formation of a village, in which they might learn the advantages of living in a community. The Indians were taught various useful arts, and after several years were admitted as church communicants, previous to which they were required to give an account of their conversion and faith at a public examination.

In "A Further Account," published in 1659, there are sermons or short discourses of several converted Indians. Five Indian youths were receiving an education at the Cambridge grammar-school in Massachusetts, two of whom had been examined in Latin before the magistrates and elders of the place. In 1670 several "praying towns," as the villages of the converted Indians were called, had been erected under Eliot's auspices. In 1674 there were four "praying-towns" in Massachusetts. Eliot died in 1690, at the age of eighty-six. Mather, Bourne, Sergeant, and Brainerd succeeded each other in the work of bringing the Indians to a knowledge of Christianity, but none of them laboured so successfully as Eliot. Brainerd was an ardent and enthusiastic labourer, and exhausted himself by his extraordinary exertions. He was sent to America in 1742, by the "Honourable Society in Scotland for promoting Christian Knowledge," and died in 1747.

By the end of the 17th century the population of the English settlements in America had greatly increased, while the means of spiritual instruction had not been proportionally extended, and the small number of Episcopal churches which existed roused the friends of the Church of England at home to make exertions to supply the deficiency. While the conversion of the natives had chiefly attracted the attention of pious persons, it was found, in 1675, that "there were scarce four ministers of the Church of England in all the vast tracts of North America." Compton, bishop of London, prevailed upon Charles II. to allow 20*l.* for passage-money to ministers and schoolmasters who should go out to supply the deficiency; and a royal gift of 1200*l.* was procured to purchase a Bible, Prayer-Book, and the Homilies, for each parish. In 1679 it was stated that there was not a minister of the Church of England either in Pennsylvania, the Jerseys, or New England, and that these settlements were only occasionally visited by the chaplain to the fort at New York. Many families had never attended any public religious service since they left England. The Society for the Propagation of the Gospel in Foreign Parts originated in the desire to supply the spiritual destitution of these and other settlements, and received a charter of incorporation on the 16th of June, 1701. The Society was composed, by charter, of the chief prelates and dignitaries of the Church, and several of the most eminent persons in the state. Archbishop Tennison was the first president. The amount received by the Society in the first four years after its incorporation was—first year, 452*l.*; second, 575*l.*; third, 864*l.*; fourth, 1343*l.* The efforts of the Society were at first directed to building churches and sending out orthodox clergymen to the colonies. At the same time, and also before the Society was chartered, strong representations were made to the government of the important political influence which the French Jesuit missionaries exercised in Canada in keeping tribes neutral or in alliance with France; and at a court held at St. James's, April 3rd, 1700, representations being made to the effect that the five nations of Indians bordering on New York might probably be seduced by the French, the council came to the opinion, that two Protestant ministers, with a competent allowance, should dwell amongst them, in order to instruct them in the true religion and confirm them in their duty to her majesty. The state of the Indians was one of the objects to which the charter directed the attention of the Society, but its funds were for some time expended in maintaining ministers within our own settlements.

About the year 1680 the condition of the negro slaves in our settlements began to excite attention. In 1680 Morgan Godwyn, "some time student of Christ Church, Oxon," wrote a 'Persuasive to the Instructing and Baptising of the Negroes and Indians in our Plantations.' Towards the close of his life, Eliot had begun to instruct the negroes in New York; and in 1704 the Society for the Propagation of the Gospel established catechising schools in New York for the negroes, the number of negroes and Indians in the city being then 1500. In 1727, Gibson, bishop of London, addressed the missionaries in the English plantations, exhorting them to assist in instructing the negroes. In a sermon preached by Beilby, bishop of Chester, in 1783, before the above Society, the civilisation and conversion of the negroes were announced as one of the great objects of the Society.

The Danish and Moravian missions were the first two in which the chief object was the conversion of the heathen; for the Society for Propagating the Gospel was for some time limited in its operations, and may be regarded in the early part of its existence rather as a "Pastoral Aid" Society. The Danish Missions owed their existence to Frederick IV., who about 1705, became anxious that the gospel should be preached in the Danish settlements in the East Indies. Ziegenbalg and Plutsch, who had been educated at Berlin, were the first missionaries sent out; they proceeded to Tranquebar, on the Coromandel coast. The Danish missionaries immediately established schools, and prepared tracts and small works in the Malabar language. In 1707 their first church was consecrated. In 1708 the translation of the Testament was begun, and completed in 1711: but they had no press, and were obliged to employ transcribers. The Society for the Propagation of the Gospel opportunely forwarded a

z z

printing-press, a hundred reams of paper, six cwt. of type, and engaged a printer for the mission. In 1714 the missionaries had published thirty-four different works in the Malabar language, and fourteen others, written by Catholic missionaries, were used by their scholars and converts.

The Moravian missions commenced in 1731, and were supported with singular activity and perseverance. Count Zinzendorf, the founder of the Moravians, or United Brethren, while attending the coronation of Christian VI. at Copenhagen, saw two natives of Greenland who had been baptised by Egede, who had been sent thither in 1721 by the Danish society, and he heard with regret that the government was on the point of abandoning the mission in that country. He exerted himself, and with the assistance of the Brethren successfully established missions in Greenland, as also in the West India Islands, Lapland, Tartary, Algiers, Guiana, and in North America, for the Indians, though experiencing considerable persecutions from the European settlers in Georgia, Pennsylvania, New Jersey, and other places. The efforts of the Brethren were directed to many other places with various success.

In 1742 the Brethren residing in London formed themselves into a "Society for the furtherance of the Gospel." This Society was revived in 1818.

As it is manifestly impossible to detail all the operations of the various societies, we confine ourselves to giving the following table of the date of their institutions, an outline of the places to which their chief efforts are directed, and the amount of the last annual income of each, wherever it can be obtained:—

UNITED KINGDOM.

Inst.	Title of Mission.	Scenes of Operation.	Income.
			£.
1701.	Society for the Propagation of the Gospel in Foreign Parts.	India, Ceylon, South Africa, Guiana, &c.	90,000
1786.	Methodist	West Indies, West and South Africa, India, Ceylon, China, Australia, Columbia, Fiji Islands, France, Switzerland	25,000
		Home receipts	106,834
		Foreign „	33,170
1792.	Baptist	India, Ceylon, China, West Indies, Africa	29,546
1795.	London	South Africa, India, China, Madagascar, West Indies, Guiana, Polynesia.	
		Home receipts	80,898
		Foreign „	14,281
		Special—China	8,141
		„ India	4,927
1796.	Scottish and Glasgow (United Presbyterians and Free Church).	India, Jamaica, Caffraria	
1796.	Methodist New Connexion .	Canada, Australia, China, &c.	7,611
1799.	Church of England	India, Ceylon, China, Mauritius, Africa, Egypt, North-west America, Turkey, Palestine, Greece, Asia Minor	132,052
		Special for India	13,576
1809.	London Society for Promoting Christianity among the Jews.	Europe, Palestine, Turkey, Egypt, Persia, and in Great Britain	32,451
1815.	General Baptist	India (Orissa)	
1825.	General Assembly of Church of Scotland.	India, the British Colonies, Jews in Germany, Turkey, Egypt	2,260
1834.	Society for Female Education in the East.	India, China, South and West Africa, Levant	2,955
1835.	United Presbyterian Synod	India, Canada, West Indies, West Africa, Caffraria, the Jews	25,738
1836.	London City Mission . . .	London, and large towns . .	35,473
1840.	Welsh Foreign	India (north-east of Bengal)	
1840.	General Assembly of Presbyterian Church, Ireland.	India	
1842.	British Society for Propagation of the Gospel among the Jews.	Europe, Palestine, North Africa, and in Great Britain	5,263
1842.	Reformed Presbyterian Synod.	New Hebrides	
1843.	General Assembly of Scottish Free Church.	India, Caffraria, British Colonies, the Jews	60,578
1844.	Free Presbyterian Church in England.	China	
1844.	Patagonian	Patagonia	
1845.	Naval (for Loochoo)	Loochoo	
1850.	Chinese Evangelisation . . .	China, Penang	
1851.	Colonial Church and School	British America, India, South Africa, Australia, West Indies	27,085

Of the missionary societies of the Continent and America we do not

give the receipts, but the American Board of Foreign Missions, and the General Assembly of the Presbyterian Church Mission, have the largest incomes among the societies of the United States; the receipts of the first ranging betwixt 70,000*l.* and 80,000*l.* a year; those of the second betwixt 40,000*l.* and 50,000*l.* All the others are small, none of the annual incomes exceeding 10,000*l.*, and some are less than 1000*l.* Of the continental missions, the United Brethren and Berlin Missionary Society are the chief; of these the incomes reach about 15,000*l.* each, while the total of all the rest does not much exceed that sum. The "Institut pour la Propagation de la Foi," which was established at Lyon in 1822, and whose chief branches are at Lyon and Paris, publishes yearly reports, from which it appears that the missionary labours include Great Britain and Ireland, British America, Australia, the United States, India, Ceylon, China, with other places in each quarter of the world. Their income ranges betwixt 150,000*l.* and 160,000*l.* a year.

CONTINENTAL.

Instituted.	Title of Mission.	Scenes of Operation.

1845.	American Indian Mission . .	United States.
1848.	Synod of Presbyterian Church in Nova Scotia.	New Hebrides.

In addition to missionary labours, many of the societies of the United Kingdom have caused to be produced and printed translations of the Scriptures and other works into the native languages. Notices of most of these will be found under BIBLE SOCIETIES.

MIST. The vapour of water, when mixed with air of the same or a higher temperature, is invisible; but when the temperature of the air is reduced below that of the vapour, the vapour becomes visible, and forms a *mist*. Water, in the state of vapour, is continually rising into the atmosphere at all the usual temperatures. At and even below the freezing-point water evaporates, and ice and snow, in a dry atmosphere, gradually disappear without becoming sensibly liquid. But as heat is the sole cause of the conversion of water into vapour, the quantity produced other things remaining the same, is in proportion to the temperature; so that in very hot weather the air is not easily saturated with vapour, and in cold weather evaporation is slow: thus, there is more vapour in the air in summer than in winter, and in hot countries than in temperate climates, in all cases where similar surfaces of water are exposed to the sun's rays. Indeed, it has been found

that the quantity of vapour in the air diminishes nearly uniformly with the temperature from the equator to the poles. But as the quantity of vapour which the air will hold at any given temperature is limited, whenever that quantity is near or at the point of saturation, a very small reduction of temperature renders the air misty, and a further reduction converts the vapour into rain.

As every reduction of the temperature of the air has a tendency to destroy the transparency of the vapour which it contains, the atmosphere in our variable climate is seldom very clear. Soon after sunrise however, in fair weather, the vapour near the earth having been precipitated by the night-cold in the form of dew, and the sloping rays of the sun having little power to raise more vapour, the air is almost perfectly transparent, and every object has a clearness and sharpness of outline which it never has at any other time of the day.

When the mist is very thick, it is called a *fog*. The fogs which frequently occur in London in the winter arise from the large quantity of vapour produced by a great city being condensed by cold: and as it is not carried off by winds, it is mixed with the smoke, and forms a thick mass in and about the town; while at a short distance the air is often quite clear, and the limits of the fog may be distinctly observed. The comparative cold of the local atmosphere in the valley of the Thames below London, and its extension up the river, are also concerned in the production of London fogs.

The preceding is a very general view of the nature of mist and its production. On our rivers and seas, towards the end of summer, throughout the autumn and the beginning of winter its frequency and amount are remarkable, and are the cause of much delay and risk to the navigator. The immediate and topical dependence of the formation of mist, however, on the ordinary terraqueous surface, is upon the temperature of rivers and collections of water. This was made a special subject of attention by Sir H. Davy, in his second journey on the continent of Europe, in 1818, and he published the results in the 'Philosophical Transactions' for the following year, pp. 123-131. He thus describes the process by which mist is formed:—"As soon as the sun has disappeared from any part of the globe, the surface begins to lose heat by radiation, and in greater proportions as the sky is clearer; but the land and water are cooled by this operation in a very different manner: the impression of cooling on the land is limited to the surface, and very slowly transmitted to the interior; whereas in water above 45° Fahr., as soon as the upper stratum is cooled, whether by radiation or evaporation, it sinks in the mass of fluid, and its place is supplied by warmer water from below, and till the temperature of the whole mass is reduced nearly to 40° Fahr. the surface cannot be the coolest part. It follows, therefore, that wherever water exists in considerable masses, and has a temperature nearly equal to that of the land, or only a few degrees below it, and above 45° Fahr. at sunset, its surface, during the night, in calm and clear weather, will be warmer than that of the contiguous land; and the air above the land will necessarily be colder than that above the water; and when they both contain their due proportion of aqueous vapour, and the situation of the ground is such as to permit the cold air from the land to mix with the warmer air above the water, mist or fog will be the result; which will be so much the greater in quantity, as the land surrounding or inclosing the water is higher, the water deeper, and the temperature of the water, which will coincide with the quantity or strength of vapour in the air above it, greater."

He proceeds to detail some observations in proof of the correctness of this view, made on the Danube from Ratisbon to Vienna, and at the junctions with it of the Inn and the Ilz; on the Rhine, the Raab in Hungary, in Carniola, on the coast of Istria, and in Italy, including the Po and the Tiber, and the small lakes in the Campagna of Rome.

After mists have been formed above rivers and lakes, their increase seems not only to depend upon the constant operation of the cause which originally produced them; but likewise, Davy inferred, upon the radiation of heat from the superficial particles of water composing the mist, which produces a descending current of cold air in the very body of the mist, whilst the warm water continually sends up vapour; it is to these circumstances that the phenomena must be ascribed of mists from a river or lake, sometimes arising considerably above the surrounding hills. When rivers rise from great sources in the interior of rocks or strata, as they have the mean temperature of the climate, mists can rarely form upon them, except in winter, or late in autumn, or early in spring. Great dryness in the air, or a current of dry air passing across a river, will prevent the formation of mist, even when the temperature of the water is much higher than that of the atmosphere.

This topical cause of the deposition of moisture from the atmosphere is of considerable extent and variety in its modifications, and is not without effect in the economy of nature, "for verdure and fertility, in hot climates, generally follow the courses of rivers, and by the operation of this cause, are extended to the hills, and even to the plains surrounding their banks."

When the vapours in the upper regions of the atmosphere are condensed and become visible, they form clouds. [CLOUD.] When those near the surface of the earth are condensed upon cold objects, they form *dew* and *hoar-frost*. [DEW; HOAR-FROST.]

MITRE (from *mitra*, *μίτρα*, a head-band or diadem), the crown or

pontifical ornament worn on the head by archbishops and bishops, and in some instances by abbots, upon solemn occasions.

The original meaning of *Mitra*, as it appears from Homer, is a "band" or "belt," worn by warriors to protect the lower part of the body. It is used by later writers to signify a band for the head, worn by the Greek females; and also more particularly to indicate the head-dress worn by Lydians, Phrygians, and other nations of Asia Minor, which is sometimes called the Phrygian cap or bonnet.

It is not known when it was first adopted by the hierarchy, but it was probably not till the 7th century, when bishops were first established by the Roman emperors. Gough, in his 'Sepulchral Monuments,' vol. i., p. cliii., says, "The mitres of Christian prelates were borrowed from the Apex or Tutulus of the Flamen Dialis." The peculiar form of the episcopal mitre, divided at the sides and pointed in front, is believed to be a symbol of the parted or cloven tongues, "like as of fire," which sat upon each of the apostles on the day of Pentecost. The pope has four mitres, which are more or less rich according to the solemnity of the feast-days upon which they are to be worn. The cardinals anciently wore mitres, before the hat, which was first granted to them by the council of Lyon in 1245. Furetière, in his 'Dictionnaire Universelle,' says that it was not till the 11th or 12th century that abbots were allowed to wear mitres. The Premonstratensians procured a constitution, which was confirmed by Pope Innocent III., that all the abbots of that order should wear them.

In England the mitre was certainly used by bishops as early as the time of the Saxons, and continued as long as the Roman Catholic religion was that of the state. Since that time (except at the coronation of Elizabeth), the mitre has appeared only as an heraldic ensign, surmounting the episcopal coat of arms, unless perhaps in some occasional instance, such as Evelyn refers to in his 'Diary,' under 20th Dec. 1661. "The bishop of Gloucester preached at the abbey at the funeral of the bishop of Hereford, brother to the duke of Albemarle. It was a decent solemnity. There was a *silver mitre* with episcopal robes borne by the herald before the herse, which was followed by the duke his brother, and all the bishops, with divers noblemen." Mitres were however borne before the herse at a bishop's funeral much later than the occasion adduced by Evelyn. Anciently, the mitre, as an ornament, seems to have descended from bishop to bishop. Among the Cottonian manuscripts is an order, dated 1st July, 4th Hen. VI., for delivering to Archbishop Chicheley the mitre which had been worn by his predecessor. That it was an ornament of great expense may be gathered from the circumstance that Archbishop Pechelham's new mitre, in 1288, cost 173*l.* 4*s.* 1*d.* (See Ducarel's 'Excerpts from the Lambeth Registers; MS. Brit. Mus.')

As an heraldic ornament the mitre of a bishop is only surrounded by a fillet set with precious stones. The archbishop's mitre issues from a ducal coronet, but this appears to be an innovation of comparatively recent date.

MITTIMUS, a legal term applied to certain writs and warrants in which the word *mittimus*, "We (the King) send," is expressed or implied.

If a record of one court be, for any purpose, required to be transmitted to another, as one court can exercise no direct authority over another, the course is, for a writ to issue out of Chancery, requiring the court in which the record is to certify the same to the Crown in Chancery: and when the record is removed into the Court of Chancery by this writ (of *certiorari*), it is sent from the Chancery to the court in which it is wanted by writ of *mittimus*. The term is, however, in more frequent use as applied to the warrant by which magistrates commit and *send* persons charged before them with offences to the proper custody, in order that they may be forthcoming to answer the charge, when ripe for judicial decision.

MIXTURES, in Pharmacy, signify liquid medicines consisting of several ingredients, either in a state of mechanical suspension in some viscid medium, or in a state of complete solution. In preparing these, care must be taken not to mix in the same prescription substances which exercise an antagonising action on the body, or which are incompatible, from one ingredient decomposing another. Sometimes, however, it is the substance resulting from the decomposition of one or more of the constituent articles which is desired, as in the compound mixture of iron, and in this case decomposition of the materials is indispensable. [INCOMPATIBLES.]

No greater quantity of a mixture should be prepared at one time than is likely to be used before the compound is spoiled, either by the atmosphere, if the materials are of a vegetable kind, or by the action of the various ingredients on each other.

MNEMONICS. [MEMORY.]

MNEMOSYNE. [MUSES.]

MOABITES, a people descended from Moab, the son of Lot by his elder daughter (Gen. xix. 37), and consequently related to the Ammonites, with whom we find them closely connected in their subsequent history. [AMMONITES.] The earliest accounts represent them as dwelling in the country on the east of the Dead Sea and the river Jordan, on both banks of the river Arnon (Wady Modjeb), from which they had driven out the Emim, who were said to be a tribe of giants. (Deut. ii. 11; Gen. xiv. 5.) The plains on the east of the Jordan near its mouth were called from them the Plains of Moab. (Numb. xxii. 1; Josh. xiii. 32; Deut. xxxiv. 1, 8.) At the division of Canaan among the

tribes of Israel, this tract of country was given to Reuben and Gad; but by the command of God, the Israelites left the Moabites in undisturbed possession of their country. (Deut. ii. 9.) During the existence of the Hebrew kingdoms, the relations of the two peoples were sometimes friendly, but more frequently hostile, and the details are given or alluded to in many parts of the historical books of the Old Testament. According to Josephus, the Moabites were reduced to subjection by Nebuchadnezzar in the fifth year after the destruction of Jerusalem. ('Antiq.' x. 9, 7.) Their name ultimately disappeared in that of the Arabians.

The Moabites were a pastoral people. (2 Kings, iii. 4.) Their country was well adapted for rearing cattle, and also produced corn and wine. (Ruth, i. 1; Is. xvi. 8-10.) It contained many mountains and fertile valleys, and was well watered by the Arnon, the Zered, and other rivers which fall into the Dead Sea. The land is now desolate, the sand and salt of the desert and the Dead Sea continually encroaching upon it; but the number of ruins of towns,—the remains of ancient highways, often paved, with milestones bearing the names of some of the Roman emperors,—the forms of the ancient fields, which may yet be traced,—all testify to the former existence of a large population, which the fertility of the land was able to support, and which must have continued to exist to a period much later than the time when the Scripture accounts of this people cease.

Ar was their capital, called also Rabbah-Moab, and the ruins still bear the name of Rabba. The ruins are upon a low hill in a plain through which runs the stream Boni-Hamed, which falls into the Dead Sea. They occupy a space of about a mile in circumference, with many remains of private houses, but none entire. The principal objects are a temple or palace, of which a wall and some niches yet remain, the gate of another building, and two Corinthian columns. As there were no springs in the district, two reservoirs were formed, of which the largest has been cut out of the solid rock. There are also several cisterns.

(Burckhardt's *Travels in Syria*; Irby and Mangles's *Travels*; Mac-michael's *Journey*; Lord Lindsay's *Letters*.)

MODE, in ancient music, is the order of the sounds forming what may, in modern language, be called the different scales.

The ancients differed exceedingly among themselves in their definitions and on the divisions and names of their modes or keys. Obscure on every musical subject, they are nearly unintelligible on this: they all agree, however, that a mode is a certain system of sounds, and it appears that this system or succession is in itself nothing but a given diapason, or octave, made up of all the intermediate sounds, according to the genus.

In the earliest Greek music whereof we have any account there were but three modes, of which the key-notes were at the distance of one tone from each other. The lowest of these was called the *Dorian*, the highest the *Lydian*, and the *Phrygian* was placed between the other two. Subsequently, by dividing the tones into semitones, two other modes were produced, the *Ionian* and the *Æolian*, the first of which was placed between the *Dorian* and *Phrygian*, and the second between the *Phrygian* and *Lydian*. At length, by extending the system above and below, new modes were established, which took their names from the former five, adding the preposition *hyper* (ὕπερ, above) for the higher, and *hypo* (ὕπο, below) for the lower. Thus the *Lydian* mode was followed by the *Hyper-Dorian*, the *Hyper-Ionian*, &c., in ascending; and after the *Dorian* mode followed the *Hypo-Lydian*, the *Hypo-Æolian*, &c., in descending.

In the 'Essai sur la Musique,' by M. Laborde, is a comprehensive table of the modes, with the Greek musical characters, &c.; and in the 'Philosophical Transactions' (vol. li., part 2) will be found a table of the same kind, to "show the tuning of the lyre in every mode," by Sir Francis Styles, an industrious inquirer and a learned original writer on the subject.

Of the then existing modes Plato rejected some, thinking them capable of operating prejudicially on the manners, and Ptolemy reduced the number to seven; the latter, therefore, confined all the modes within the compass of an octave, of which the *Dorian* mode is the centre, so that the *Mixo-Lydian* was a 4th above, and the *Hypo-Dorian* a 4th below; the *Phrygian* a 5th above the *Hypo-Dorian*; the *Hypo-Phrygian* a 4th below the *Phrygian*; and the *Lydian* a 5th above the *Hypo-Phrygian*: whence results the following order:—

1	.	.	.	F	.	.	.	Mixo-Lydian.
2	.	.	.	E	.	.	.	Lydian.
3	.	.	.	D	.	.	.	Phrygian.
4	.	.	.	C	.	.	.	Dorian.
5	.	.	.	B	.	.	.	Hypo-Lydian.
6	.	.	.	A	.	.	.	Hypo-Phrygian.
7	.	.	.	G	.	.	.	Hypo-Dorian.

From these seven modes, with the *Hypo-mixo-Lydian*,—added, it is said, by Guido,—were formed the eight ecclesiastical modes, or tones, of the Roman Catholic Church.

Mode, in modern musical language, signifies the same as Key; but, though a far more convenient term, is very rarely used in that sense in this country. [KEY.]

MODELLING in clay is so completely a practical art, and depends so much on the experience and formative skill of the modeller, that,

beyond a few remarks on the necessary consistency of the clay, nothing more can be given here than an account of the nature and uses of the tools, and some description of the sculptor's process.

The tools, called modelling tools, are made of wood and wire, but no tool is more useful than the finger; indeed tools have been invented as mere aids to the fingers, and are designed to do what they cannot perform. Wire tools are the most useful, being fashioned into loops of various shapes and sizes, round and angular, and fixed into wooden handles. They accomplish any required form without driving the clay on to any already modelled part, the superfluous clay remaining in its place while the wire passes under it and until the tool is removed, when it either falls of its own weight, or is removed by the slightest touch of the modeller. The wire tools are most efficient when applied to concave surfaces, especially those in the close or narrow folds of draperies: the wire is sometimes notched or indented, to give a rough surface to the clay. The wooden tools are made of box and ebony, of various shapes and sizes—curved, straight, pointed, rounded, and flat and broad; the broad tools being notched, and designed chiefly for working the large convex masses, or large folds in drapery. In modelling a bust, especially the features, great nicety is required, and the modeller must be particularly careful not to injure what is already done, by retouching with the tool while clay is adhering to it, or he may risk the complete destruction of his work: the adhering clay will drive up the surface. A good method to guard against this accident is to keep the wooden tools which are used for the finer work soaked in oil; the clay is then not liable to adhere, and much time is accordingly saved in finishing the model. The above is perhaps, without practical demonstration, all that can be usefully said about the working tools.

The clay used is common potters' clay, but should be of the best quality. It must be so wet that it will not stand in a mass much higher than its own width without support. The clay adheres much more to the tools when wet, but it is at the same time much more easily and quickly worked, a matter of great consequence, as the patience of the artist is less tried, and some expenditure of time is saved. The supports for the clay are a most important consideration, for if not properly attended to, the finished work, the fruits of months of labour, might suddenly fall to pieces by its own weight. The support of a figure of the heroic or ordinary size (seven feet) is comparatively easy, but this also exacts strict attention, especially if in any very active or unusual attitude. Sculptors generally model figures of the ordinary size upon a bench or stand called a *banker*, about thirty inches high, and about thirty inches square,—for a bust it must of course be much higher; above this a solid circular plinth is fixed on a wooden box, and is revolved upon six or more wheels, or what are better, short slightly conical rollers, fixed to the plinth near the circumference: the plinth moves more easily on such rollers than wheels, and the rollers afford a more solid support and last longer. A revolving plinth is necessary to enable the sculptor to see his work on all sides in any light, and it enables him to work on all parts, in one spot, or in the same light. On the centre of the plinth there must be fixed vertically a strong iron bar, about the height of a man, and from about six to ten inches in circumference, according to the weight of the figure; it must necessarily be strong and firmly fixed, as it is the main support of the whole skeleton of supports. In loosely draped figures, which are proportionally heavy, it is advisable to fix a vertical beam of wood to the main iron bar; for though the bar will keep the clay perpendicularly in its place, it is no provision against the sinking of a great mass; and the quantity used in some figures, even of the heroic size only, amounts to about two tons. Two cross pieces of wood must be fixed to the main bar at the shoulders and the loins, from which the supports of the arms and legs must be started; and a third piece may be fixed in the middle to diminish the weight of clay: the supports of the legs must be bars, straight or bent, according to the position of the legs; but the supports of the arms, when not detached from the body or drapery, may generally be made of twisted thick copper wire, small pieces of wood being twisted in with it at short intervals and at right angles, like the pieces of paper in the tail of a boy's kite. The fingers, if separated, will require similar care; indeed the clay should be gradually built up against a complete skeleton of supports and sufficiently strong not to yield in the least to the weight of the clay when the model is finished. The building of such a skeleton for a figure of the heroic size is often the work of a week or more, and it would be always advisable for the young sculptor, in modelling his first figure, to procure some experienced hand to construct his skeleton of supports for him. If an arm is slightly elevated, and detached from the figure, the support might be so contrived as to allow the arm to be removed at pleasure, which would enable the sculptor to model the part beneath it with much greater ease, and would considerably diminish the risk of injury to the arm. The contrivance is easily accomplished, for nothing more is required than a pipe or tube in the shoulder support, which could receive and hold firmly the skeleton support of the arm, which might be a bar of wood or of metal; or thick or twisted wire, when of a small size. In modelling a bust very little support is necessary, an upright piece of wood with a cross-bar at the shoulders being quite sufficient; but a small cross-bar at the head would do no harm.

Another essential part of modelling is preserving the moisture of the clay, which should be always uniform if possible; it must never be allowed to dry, and it can be kept moist with very little trouble.

MODELS, ARCHITECTURAL.

713

While the modeller is at work, and the figure is exposed, especially in warm weather, he should repeatedly sprinkle it with water. A plasterer's brush is the best instrument for this purpose, and much superior to a syringe or the mouth, which some sculptors formerly used to apply as a squirt, even in the presence of their sitter, when modelling a bust: Nollekens, according to his biographer Smith, adopted this elegant mode of keeping his clay moist while modelling the bust of George III., and in the king's presence. Bacon, on a similar occasion, used a silver syringe. At night time, or when the artist is not at work on the model, it should be covered over with a wet cloth or sheet. A figure may be kept moist for a long period without adding water, provided the air be kept away from it; this may be done by an oil-silk or any air-proof bag, which can be made fast to the plinth of the banker by clay. Sculptors generally model the flowing draperies from lay-figures. When the model is complete, the next process is to take the cast, to work the marble from, or to make other casts from. The whole model, while wet, must be covered, in two or three masses, or more if necessary, with plaster of Paris; when this is fixed and dry, the whole may be separated at the joints, with out any regard to the preservation of the model, for when the mould is taken the model is no longer of any value. When the clay is completely removed from the mould, the component parts of the mould must be again put together, and in the place of the original clay it must be filled with plaster of Paris, and when the cast is well set, the mould may be carefully broken off in fragments, and the cast is exposed, and complete, the finished work. If casts of it are required, a new working mould, or *safe mould*, as it is termed, must be taken, in many parts. If the figure is to be executed in marble, it is copied by the carvers, with the assistance of the pointing-machine, which is so contrived that it can diminish or increase the scale of the model with perfect ease and nicety. It is always best to make the model of the size of the intended figure if practicable, because any error in a small model becomes multiplied in a larger one in proportion to the difference of size. Flaxman was in the habit of making small models, and he had in consequence sometimes immense labour to go through to diminish errors in the full-sized marble work: it is hardly possible to completely rectify them.

The ancient sculptors used to bake their models, but this is not so good a plan as making plaster casts from them, though less troublesome and much cheaper: the clay in drying shrinks, and is apt to crack, and certainly never comes out of the oven the same shape that it was when put into it, or at least when originally modelled. These baked models are called *terra-cotta* (*baked earth*) figures, are extremely numerous, and are generally of small dimensions, but there are a few of a large size in various European museums. The ancients made also moulds of clay, which they likewise baked, and they formed their casts by pressure of clay into these: this practice of pressing clay, or any malleable substance, into a mould is still occasionally had recourse to in works of fine art, and constantly in the potteries, and by framemakers.

The ancients used also wax for casting and in forming their models, especially those of the small bronzes, which are still so exceedingly numerous, and it is the common material used by goldsmiths and medalists. Modelling wax is prepared by melting virgin wax with a very small quantity of Venice turpentine and flake-white in fine powder: if coloured wax is required, a colour in fine powder must be substituted for the flake-white. The tools used in modelling in wax are made of wood and ivory, and have the same shapes as those of wood, already spoken of, for modelling in clay. Other processes in the art of sculpture will be found explained in the articles BRONZE; FOUNDRY; SCULPTURE; and WAX MODELLING.

MODELS, ARCHITECTURAL. Besides the usual delineations upon paper showing the plans and different parts of a building, and their details in elevations, sections, and working drawings [DESIGN; ARCHITECTURE], a solid representation or miniature facsimile of the proposed edifice is sometimes formed, in order to give a more distinct idea of it than can be obtained from a number of separate drawings by those who are unable to comprehend them perfectly, and combine them mentally, so as to figure to themselves a complete and distinct image of the whole. Models of this kind are variously executed, and more or less finished up, as may be required. Sometimes they are of wood, either coloured or not; and if economy is studied, the capitals of the columns, the cornices, and all other decorative parts, are merely blocked out in the rough, the mouldings and ornaments being omitted. But the material now more generally used is plaster of Paris, because columns and other parts that require much carving may be cast in moulds, and afterwards finished up with comparatively very little trouble or expense. Another material employed for making architectural models is card-board, applied in surfaces of various thicknesses; and although it seems fitted only for very plain buildings, it is capable of being wrought so as to express even the minute and elaborate tracery and other ornaments in Gothic architecture: models thus formed are less beautiful than those of plaster, but they are less susceptible of injury, and may be more easily coloured to represent the different materials—stone, brick, wood-work, slate, &c. They are however more expensive, being attended with much greater labour, and requiring to be built up, as it were, like the edifice itself.

Models are by no means so generally made use of as they ought to

be, on account of their expensiveness; but when a building of great magnitude is to be erected, the cost of a model, although it may be considerable in itself, becomes a mere trifle in the sum-total. Where merely the façade of a building will be exposed to view, a model may be dispensed with, as a simple elevation will answer the purpose quite as well. But for one that is insulated, or is at all complex, a model becomes desirable: the same again if a façade is composed of many parts or surfaces, some projecting, others retiring, the effect of which cannot else always be so distinctly foreseen as it ought to be, except perspective drawings be made of it from several different distances and points of view. For showing the internal parts of a building, models are of comparatively little use.

Portrait models of celebrated edifices are frequently introduced in libraries and galleries, either as restorations of the original structures, or as showing them as dilapidated by time. For those of the last-mentioned kind, cork is the material usually made use of, it being well calculated to express of itself the ruggedness and flaws of decayed stone buildings.

MODES, Ecclesiastical (*Tuoni Ecclesiastici*), or *Tones of the Church*. In what is called the Gregorian Chant there are eight modes or tones—four Authentic and four *Plagal*. [AUTHENTIC; PLAGAL.] The Authentic modes are the Dorian, Phrygian, Lydian, and Mixo-Lydian of the ancients, which correspond, according to Dr Burney, to D and A minor, C and D major, of the moderns. These were chosen by St. Ambrose, about the year 370, for the church of Milan. The Plagal modes are the Hypo-Dorian, Hypo-Phrygian, Hypo-Lydian, and Hypo-Mixo-Lydian, corresponding to G and A minor, F and G major, and were added by St. Gregory about 280 years after the adoption of the former. It must be observed, that the Gregorian Chant has its dominant, but takes this name from being the note most often heard: hence it is frequently mentioned in the Gregorian schools as the key-note.

MODILLION (Architecture), an ornamental member in the Corinthian cornice, resembling a small bracket placed horizontally, that is, with its back against the soffit of the part it supports, in which respect it differs from the console, which is placed upright, with its back against the vertical face of the part to which it is attached, and with its larger or convex end uppermost, whereas the larger end of the modillion is placed backwards, and its smaller one in front. Yet though they thus far differ both as to the mode and the purpose of applying them, and also as to their details, in general form the modillion and the console closely resemble each other, the face being composed of a curve of contrary flexure. Modillions are placed beneath the corona of the cornice, and although sometimes omitted out of parsimony, are indispensable to the character of the order, being quite as much distinguishing marks of its entablature as mutules are in the Doric and dentils in the Ionic cornice. [See the cuts in the article COLUMN, cols. 47 and 52.]

MODULATION, in Music, is a changing of the key, or *mode*, during the progress of a composition. The word is derived from the Latin verb *modulari*, to compose or sing in measure, melody of some sort being inferred.

Though it is not quite clear what the ancients meant by the term *modulatio*, yet the presumption is that they signified by it the rise and fall of the voice (*accentus*) and the measure of the syllables in recitation and declamation, altogether amounting to a kind of singing; and this we are inclined to think was the boundary, or nearly so, of their proficiency, and what they chiefly aimed at, in the vocal art.

In modern music, Modulation is a most important element, and in proportion to its importance should be the manner of treating it here; but limited as we are in space, we must be confined to some general remarks, illustrating these by a few brief examples.

Modulation may be divided into Simple, Chromatic (or extraneous), and Enharmonic. Simple Modulation is a change from a given key to another nearly related to it, namely, its fifth, fourth, relative minor, or relative minor to its fifth; and this modulation, not to be abrupt, is effected by at least one intermediate chord, which must belong to the harmony of the key into which it is intended to pass. Examples in four parts:—

The close resemblance of the scales of G, F, A minor, and E minor, to the scale of C, renders the modulation easy and natural; hence we have termed it *simple*. And it must now be observed, that the natural

major key is here chosen as the diverging point merely on account of its apparent simplicity; any other would have answered the purpose, provided the same relations had been preserved. Thus, for instance, from the key of E $\flat$ to its fifth B $\flat$, is relatively the same as from C to G. Example:—

Chromatic Modulation is the change from a given key to some other not analogous to it; that is to say, to one differing much in scale, and, consequently, in signature. [SIGNATURE.] Examples:—

Enharmonic Modulation is the change from a given key to another quite unanalogous, by means of an enharmonic interval,—that is, by the same interval binominously considered; as C and B $\sharp$, A $\flat$ and G $\sharp$, &c. [ENHARMONIC.] Examples:—

In these examples we have endeavoured to show the most direct method of modulating, and, except in one instance, by means of the dominant 7th and the diminished 7th, or their inversions. By the intervention of a few additional chords, more elegant effects might have been produced, both as regards harmony and melody. But it must also be remarked that suddenness of transition is often essential to the design of the composer, in which case he takes the shortest road from key to key that the ear will permit.

It will be seen that we entirely differ from those who—perhaps misled by the word *modulatio*, and its interpretation by ancient writers—think that modulation may be carried on without any change of key. We are decidedly of opinion, though in opposition to some highly respectable authorities, that *modulation* and *change of key* are identical terms.

MODULES (Architecture), from the Latin *modulus*, as being a lesser measure than the diameter of the column, is employed to signify one half of the latter, or thirty minutes. Some writers reckon entirely by *modules* and *minutes*. Thus, instead of saying a column is eight or eight and a half diameters high, they would describe its height as being sixteen or seventeen modules.

MODUS. [TITHES.]

MOHAIR, as a material for textile manufactures, has been brought very extensively into use within the last few years. It differs from alpaca in this: that the latter is the wool or hair of a South American animal of the llama tribe [ALPACA-WOOL]; whereas mohair is the covering of a goat peculiar to Asia Minor. Twenty years ago, the quantity of mohair imported was small, but now it is very large; for the manufacturers of the north, especially the great firms in and near

Bradford, display much ingenuity in combining two or more fibrous materials, to produce what are called fancy fabrics. Under the names of vestings, pantaloons-stuffs, ponchos, shoe-stuffs, cravatings, linings, cassinets, cashmeerets, barèges, tabinets, shawl-cloths, &c., numerous fabrics are woven, in which wool, worsted, alpaca, or mohair are introduced, or two or three out of the four, according to the softness, thickness, and price of the article to be produced.

The manufacturing processes are similar in character to those described under WOOLLEN AND WORSTED MANUFACTURES.

MOHAWKS. [NORTH AMERICAN INDIANS.]

MOIDORE. [MONEY.]

MOIRÉ, a French word, having the meaning of *clouded*, *mottled*, or *watered*, is applied as a name to two different kinds of effects produced in manufactures: the one on metals, the other on textile goods.

The *moiré métallique*, first introduced by the French, presents a singular beauty and richness of appearance, something like the crystallised frost on a window in winter. The substance is formed of tinned iron plate, while the surface effect is due to the chemical action of acids. The *moiré* appears to be formed by the action of the tin on the iron at the point of contact; and the purpose of the acid is rather to render this visible than actually to produce it. Tin plate consists of a piece of sheet iron coated with a thin layer of tin while the latter is in a molten state; and the art of preparing the *moiré métallique* consists in removing all except an extremely thin film of this tin, without really exposing the iron in any part. Various acids and mixtures of acids will effect this, but the one usually employed is diluted nitro-muriatic acid. The plate of tinned iron, after being slightly heated, is washed with the acid. As soon as the workman sees the *moiré* develop itself, he plunges the sheet into cold water, and gently washes off the acid and dissolved tin with a feather or a bit of cotton wool. The time necessary to produce this action varies from one to ten minutes, according to the strength of the acid and the heat of the plate. When the *moiré* has been properly developed, and the acid and tin removed, the plate is carefully dried, and the variegated surface protected by a coating of varnish; if the varnish be white, a silvery or pearly *moiré* is produced; if coloured, richly diversified tints are obtained. A modified kind of *moiré métallique* is produced by the action of heat without acids. The plate of tinned iron is exposed to such a temperature as will melt the tin; and varied effects are produced according to the mode and rapidity of cooling. If cooled gradually, the surface presents a certain kind of *moiré* or crystallisation; if suddenly cooled by plunging in cold water, the *moiré* is different in character; if unequally cooled by water being sprinkled on certain parts, or wind blown upon them, the effect undergoes still further variations. So, on the other hand, if the heating of the plate can be so managed as to be unequal at different parts, a variation in the *moiré* results; and attempts are sometimes made to give a definite pattern to these irregularities. Nobili has produced some very beautiful *metallochromes*, or richly coloured spots on surfaces of steel, silver, and other metals; and Mr. Gassiot has varied the effects of surface thus produced; but the work is one kind of electro-metallurgy, and the effect bears little resemblance in appearance to *moiré métallique*. As a question of mere fashion, the last-named material is not now used so much as it was twenty years ago, when kaleidoscopes and ornamental boxes were covered with it; but it nevertheless remains among the list of articles available for decorative manufactures.

The *moiré* effect on textile goods, generally called *moiré antique*, is produced mostly in broad silks for ladies' dresses. It is a superior kind of that which is known as *watering* in silk; and the *moireurs*, or calenderers, endeavour to keep secret the exact mode in which it is performed. The *moiré*, clouding, or watering, is not produced in the dyeing, the spinning, or the weaving; it is a sort of calendering or pressing between two cylinders. By using cylinders hot or cold, embossed or plain, by sprinkling the silk or not with water, and by folding two layers of silk over each other either rectangularly or diagonally, various kinds and degrees of *moiré* may be produced; those threads, whether of warp or weft, which happen to be most pressed, receive most gloss; some of them become flattened; and the reflection from their surface is glossy or otherwise according to the angle at which they are viewed. Thus a very brilliant play of light and shade is produced, although all the threads may be of one colour throughout.

MOLASSES, is the uncrystallised syrup produced in the manufacture of sugar. It is suffered to drain from the casks into a cistern, in what is called the curing-house, before the sugar is sent away from the plantation. To facilitate the draining, the casks are ranged upright on a frame-work of open joists over the cistern; several holes of about an inch diameter are bored in the bottoms of the casks; and before the newly made sugar is put into the hogsheads, or, as it is called, *potted*, an equal number of plantain-stalks, or sugar-canes from which the juice has been expressed, are placed in each cask, so that the ends protrude through the holes. These stalks or canes must be of equal length with the cask, and they thus form so many channels or conduits for the passing away of the greater part of the molasses: some will always remain in the hogsheads, and, draining away by slow degrees, will in a great measure be lost during the voyage; but even after the arrival of the sugar in Europe a proportion of molasses, which is less or more according to the good or bad quality of the sugar, remains in the mass. See further under SUGAR MANUFACTURE.

Nearly all the molasses made in the English sugar colonies was formerly converted into rum by fermentation and distillation on the estates; but the price of that spirit having declined, and improvements having been made in the processes of refining sugar in Europe, whereby a large proportion of West Indian molasses has been rendered crystallisable, a considerable and continually increasing quantity of molasses is shipped for that purpose. The syrups, which ultimately remain in a liquid form after passing through the processes of a refining-house, whether the same are the produce of Muscovado sugar or of molasses, are sometimes called molasses, but are more generally known as treacle. The imports of molasses, which were only 40,000 cwt. in 1820, rose to 250,000 cwt. in 1830; in 1845 they were more than 500,000 cwt.; and in the 14 years thence to 1859, they varied from about 600,000 to 1,100,000 cwt.

MOLECULAR ATTRACTION—MOLECULAR THEORY. In chemistry it is conceived that bodies are made up of indivisible atoms, each having a definite uniform weight and a general character. The service that this theory has rendered to science may be seen by consulting **ATOMIC THEORY**. The ultimate particles of matter are termed *atoms*, the word *molecules* being applied to the constituent or heterogeneous whole. [**MOLECULE**.] If the molecular constitution of bodies were known,—that is, the specific nature of these molecules,—and the laws of the forces which retain them in connection, whether these forces be of attraction or repulsion, science would then be able to define the changes and sequences of the material universe. Various efforts have been made from time to time to construct theories on this ground sufficiently general to afford a basis for important and wide conclusions, and yet to avoid injurious restrictive conditions. According to the theory of Boscovich, matter does not consist of solid particles, but of mere mathematical centres of force. Each body is supposed to be made up of a number of geometrical points, from which emanate forces following certain mathematical laws, in virtue of which the forces become at certain small distances attractive, at certain other distances repulsive, and at greater distances again attractive. [**ATTRACTION**.] "From these forces of the points arise the cohesion of the parts of the same body, the resistance which it exerts against the pressure of another body, and, finally, the attraction of gravitation which it exerts upon bodies at a distance."

Dr. Whewell, from whom we have just quoted ('History of Scientific Ideas,' vol. ii., 1858), regards this theory as homogeneous and consistent, and thinks it probable that it may be used for investigating and expressing true laws of nature, although the attempt to identify the forces by which the particles of bodies are bound together with mechanical attraction appears to be a confusion of two separate ideas. This theory, he remarks, "may be so conceived as possibly to involve an explanation of all the powers which their parts exert (such powers, namely, as those which produce optical, thermal, and chemical phenomena); but this theory cannot supply an explanation of the mechanical properties of a body as a whole, especially of its *inertia*. A collection of mere centres of force can have no inertia. If two bodies are considered as two collections of centres of force, the one attracting the other, there is in this view nothing to limit or determine the velocity with which the one body will approach the other. A world composed of such bodies is not a material world; for matter implies not only force, but something which resists the action of force."

Representing matter as a collection of molecules or centres of force, modern chemists have used the molecular hypothesis as a basis for calculations respecting the elementary forces of bodies, supposing the properties of bodies to depend upon forces emanating from immovable points of their mass. The mechanical philosopher, also, thus treats the properties of bodies on a small scale as Newton had already done with central forces on a large scale. Newton himself remarks, in the preface to his 'Principia,' "Many things induce me to believe that the rest of the phenomena of nature, as well as those of astronomy, may depend upon certain forces by which the particles of bodies, in virtue of causes not yet known, are urged towards each other and cohere in regular figures, or are mutually repelled and recede; and philosophers knowing nothing of these forces have hitherto failed in their examination of nature." Laplace, following up this hypothesis, has shown its value, if we suppose the forces exerted by the particles to decrease so rapidly with the increasing distance from them that the force is finite only at distances imperceptible to the senses, and vanishes at all remoter points. "He has taught the method of expressing and calculating such forces; and he and other mathematicians of his school have applied this method to many of the most important questions of physics, as capillary action, the elasticity of solids, the conduction and radiation of heat. The explanation of many apparently unconnected and curious observed facts by these mathematical theories, gives a strong assurance that its essential principles are true. But it must be observed that the actual constitution of bodies, as composed of distinct and separate particles, is by no means proved by these coincidences. The assumption, in the reasoning, of certain centres of force acting at a distance, is to be considered nothing more than a method of reducing to calculation that view of the constitution of bodies which supposes that they exert force at every point. It is a mathematical artifice of the same kind as the hypothetical division of a body into infinitesimal parts in order to find its centre of gravity, and no more implies a physical reality than that hypothesis does." Dr. Whewell, to whom

we owe this quotation, refers also to Poisson's views of capillary action, and also to Wollaston's attempt to bring the doctrine of ultimate atoms to the test of observation in the case of the **ATMOSPHERE**, under which head some notice of Wollaston's argument will be found. But we may here remind the reader of Wollaston's conclusion that the observed phenomena accord with the supposition that the earth's atmosphere is of finite extent, limited by the weight of ultimate atoms of definite magnitude, no longer divisible by repulsion of their parts. We must, however, refer to Dr. Whewell's work for his objections to this line of reasoning, and conclude by naming the most important works which have of late years assisted the molecular theory, such as Gauss on 'Terrestrial Magnetism,' Ohm's 'Contributions to Molecular Physics,' in which he supposes that the ultimate molecules of matter have both simple and polar powers, and by means of this hypothesis he attempts to form a complete system from which the phenomena of light, heat, and electricity necessarily arise; Mr. Grove's work, 'On the Correlation of the Physical Forces,' is also in the same direction.

MOLECULE. Matter is supposed to be made up of indefinitely small particles or *molecules*, which in a simple substance are called *integral*, or *homogeneous*, and in a compound, *constituent* or *heterogeneous*.

MOLECULES. The smallest indivisible quantities of matter which take part in chemical re-actions. [**ATOMIC WEIGHTS**; **CHEMICAL EQUIVALENTS**.]

MOLYBDENUM (Mo). A rare metal, occurring native chiefly as the bisulphide, a mineral that, in appearance and properties, so much resembles graphite as to have been mistaken for that substance until the year 1778, when its peculiarity was first pointed out. A description of the two or three ores of molybdenum that have hitherto been discovered will be found in the **NATURAL HISTORY DIVISION**, article **MOLYBDENUM**. The method of isolating the metal from the sulphide is also there detailed. The equivalent of molybdenum is 46.

Molybdenum and oxygen form three compounds:—

- | | |
|--------------------------------------|------------------|
| 1. Protoxide of molybdenum | MoO |
| 2. Binoxide of molybdenum | MoO ₂ |
| 3. Molybdic acid | MoO ₃ |

1. *Protoxide of Molybdenum (MoO).*—*Molybdous oxide.* Obtained in the anhydrous form by the action of nascent hydrogen, and in the hydrated condition on adding ammonia to a solution of the protochloride. In the latter state it is soluble in solution of carbonate of ammonia but not in the carbonates or hydrates of potash or soda. Both varieties are of a black colour.

2. *Binoxide of Molybdenum (MoO₂).*—*Molybdic oxide.* Formed when molybdate of ammonia is strongly ignited in a covered crucible. The residue should be washed with caustic potash to remove any molybdic acid. Its colour is usually dark brown, but purple in direct sunshine. It is to a certain extent soluble in water; the solution sometimes gelatinises spontaneously. The salts of binoxide of molybdenum are red when hydrated, but in the anhydrous state are almost black. An olive green oxide, and a blue oxide of molybdenum have been described, but they are now known to be mixtures of the binoxide with molybdic acid.

3. *Molybdic acid (MoO₃),* is generally obtained by roasting the bisulphide, at a low red heat, in clay basins, but M. Brunner recommends that the pulverised mineral should be first mixed with an equal volume of quartzose sand, and the mass then roasted in a platinum capsule until it has acquired a lemon-yellow colour. After cooling, the molybdic acid is extracted by exhausting the product with ammonia. The residue from the evaporation of the ammoniacal solution is heated to low redness to expel ammonia, when molybdic acid remains as a pale buff-coloured powder. At a very high temperature molybdic acid volatilises and condenses on cool surfaces in brilliant transparent needles. Molybdic acid combines with bases to form neutral and acid salts called *molybdates*.

Molybdate of ammonia is sometimes used for detecting and even estimating phosphoric acid. It is best prepared by dissolving, with the aid of a gentle heat, two parts of pure molybdic acid and one of tartaric acid in fifteen of water and afterwards adding ten parts of ammonia (sp. gr. 0.97) and fifteen of nitric acid. The whole is heated to ebullition in a porcelain basin, when about one fifteenth of the molybdic acid will precipitate, and must be separated by filtration. The solution is then ready for detecting phosphoric acid, with which it gives a yellow crystalline precipitate of phospho-molybdate of ammonia.

Molybdenum and sulphur combine in three proportions and form *bisulphide of molybdenum*, (MoS₂) already noticed; *tersulphide of molybdenum*, or *sulpho-molybdic acid*, (MoS₃) precipitated on adding hydrochloric acid to a solution of a molybdate saturated with sulphuretted hydrogen; and *quadrisulphide of molybdenum* or *persulpho-molybdic acid*, (MoS₄). *Sulpho-molybdate of potash* (KS₂MoS₃) crystallises in magnificent iridescent crystals.

Molybdenum and chlorine form two distinct chlorides, namely, *protochloride* and *bichloride*, as well as several oxychlorides that appear to contain *terchloride* of molybdenum.

Protochloride of molybdenum (MoCl). Excess of hydrochloric acid is added to a concentrated solution of an alkaline molybdate and zinc then introduced. As soon as evolution of hydrogen commences, the

liquid becomes of a blue colour, then reddish brown, and finally black. By adding ammonia to the resulting solution and redissolving the washed protoxide in hydrochloric acid, a more pure protochloride is obtained.

Bichloride of molybdenum (MoCl_3) is obtained in deliquescent crystals on evaporating a solution of the binoxide in hydrochloric acid. In appearance it resembles iodine.

The detection of molybdenum is best effected by producing the colours mentioned under protochloride of molybdenum. It is usually estimated in the form of bisulphide, which contains 58.97 per cent. of metal.

MOLYBDIC ACID. [MOLYBDENUM.]

MOMENT. The moment of a force with respect to a point or line about which it tends to produce rotation, is "the product of the force and the perpendicular drawn from the point or line upon the direction of the force. If P be the force, and p the perpendicular, the moment of P is $P \times p$.

MOMENTUM, or MOMENT. This word has been used in various senses. It simply means a motion, the word *momen*, from *movimen*, being found in several ancient authors. *Momentum* was originally one rapid motion, whence it came to be used for a very short time; whence our word *moment*, which, in common life, means an indivisible instant of time. Thus an effect which requires a single second to produce it would not be properly momentary. But the word has passed into mechanics in its original sense of motion, and is used to signify the amount of an effect of motion, actual or conceivable. Thus we have one use in the article VIRTUAL VELOCITIES, another in LEVER, a third in MOMENTUM OF INERTIA, and a fourth, the most common of all, which we proceed to explain in this article.

The English synonym of this fourth sense is "quantity of motion," and we may observe that in this sense it is most usual, in our language, to adopt the Latin form *momentum*, instead of the abbreviation *moment*. It is impossible to give an actual definition of momentum, in simple terms: but the conception is obtained by those who observe that the effects produced by matter in motion (both notions are necessary) may be augmented either by giving the same motion to more matter, or greater motion to the same matter. Imagine a BALLISTIC PENDULUM, and suppose a bullet of two pounds weight to strike it with a velocity of 100 feet per second. The same oscillation which is thus produced, may, it is found, be produced by a bullet of one pound weight striking with a velocity of 200 feet. The same effect being produced in both cases, though by different quantities of matter and different velocities, there is something which we may assert to be unaltered by the substitution of the smaller bullet with the larger velocity. This something is the momentum, or quantity of motion, a notion of a cause which is asserted to be the same when effects are the same. This mere definition would be useless except in connection with principles observed or deduced, by which it may be applied. That there is a reality in connection with it, all who know the difference between light and heavy, as these words are frequently used, are well aware. A heavy blow, for instance, does not mean a blow with a heavy body: thus the fall of a poker may give a light blow, while that of a book of one-tenth part of its weight may give a heavy one. The difference in these cases is that of momentum.

The velocity remaining the same, the momentum or quantity of motion increases with the mass moved; and the mass remaining the same, the momentum increases proportionally to the velocity communicated. But the peculiar proposition on which the utility of the term and the notion depends is this, that in all mechanical effects produced by matter in motion, a diminution of the mass may be compensated by a proportionate increase of the velocity: that is, M being the number of units of mass, and v of velocity, as long as the product of M and v remains the same, the effect produced is the same. Thus in the preceding instance $M \times v$ is 2×100 in the first case, and 1×200 in the second. And as long as $M \times v = 200$, the same effect will be produced.

This product, Mv , is the measure of the momentum, and is generally called the momentum itself. Here (as in MASS) tacit reference is made to a unit of momentum: the equation

$$\text{Momentum of } M \text{ with velocity } v = M \times v$$

implies that a unit of momentum is that produced by a unit of mass moving with a unit of velocity.

When the body moves under the action of a continually applied force, its momentum is now often expressed by the term *dynamical effect*, by which we mean the effect of a force with reference to its time of action. Thus if a force of 1 lb., acting for one second, produce a certain dynamical effect which we may assume to be unity: then the dynamical effect produced by P lbs. acting for t seconds will be $P.t$. Now let w be the weight of the body: M its mass: v its velocity: f the rate of acceleration due to P [3rd Law of Motion]. Then $P = w = f \cdot g$: hence $P = \frac{w}{g} \cdot f$; hence dynamical effect $= P.t = \frac{w}{g} \cdot f.t = Mv$.

MOMENTUM, or MOMENT OF INERTIA. Let us conceive a system of bodies possessing weight, and immovably attached to a fixed axis, round which the whole system can turn. It is known from experience, as well as deducible from the laws of motion, that the nearer the bodies are placed to the axis, the more rotatory motion may

be communicated by a given force. The *moment of inertia* is a name given to a mathematical function of the masses in the system and of their positions with respect to the axis, on the magnitude of which the rotatory motion produced by a given pressure, acting for a given time, depends. This function is the sum of the products made by multiplying the number of units in each mass by the number of units in the square of its distance from the axis. Thus, if $m, m', m'', \&c.$ be the masses of material points situated at the distances $r, r', r'', \&c.$ from the axis, the moment of inertia is $mr^2 + m'r'^2 + m''r''^2 + \&c.$ If the body be a continuous solid, and if dm be one of the elements of the mass, at a distance r from the axis, the moment of inertia is then $\int r^2 dm$, the integration being made throughout the whole extent of the solid.

Let AB be the axis, and let a pressure be communicated to the system at the point P , and such as would, were a mass P placed there, cause the system which consists of that single mass only to revolve with a velocity v , being at the distance a from the axis. The momentum of this velocity is Pv . Let the system of $m, m',$ and m'' , in consequence of this pressure, begin to revolve with an angular velocity θ (measured in theoretical units. [ANGLE.] The consequence is, that $m, m',$ and m'' begin to revolve with velocities $r\theta, r'\theta,$ and $r''\theta$, and momenta $mr\theta, m'r'\theta, m''r''\theta$. Now, if pressures, which would just prevent this motion in the same time as the applied pressure generated it, were

applied in the opposite direction, the three pressures so applied would counterbalance the pressure at P . But [MOMENTUM] the pressures which in the same time produce motions are to one another as the momenta produced, so that if $C.Pv$ represent the pressure at P , those applied in the contrary direction at $m, m',$ and m'' , are $cmr\theta, cm'r'\theta,$ and $cm''r''\theta$. But the first acts perpendicularly at the extremity of the arm a , the others at the arms $r, r',$ and r'' . Hence $cmr\theta \cdot r + cm'r'\theta \cdot r' + cm''r''\theta \cdot r'' = C.Pv \cdot a$ or $C(mr^2 + m'r'^2 + m''r''^2) \theta = C.Pv \cdot a$.

$$\therefore \theta = \frac{Pva}{mr^2 + m'r'^2 + m''r''^2}$$

the denominator of which is what has been called the moment of inertia of the system. Hence it follows that the communication of a given pressure at a given distance from the axis of rotation will cause an angular velocity which is inversely as the moment of inertia: if the masses or their distances were increased in such a way as to double the moment of inertia, the angular velocity produced by a given pressure would be only the half of what it would have been before the change.

The moment of inertia may be represented by Σmr^2 (sum of all the terms of the form mr^2), and the whole mass by Σm . Let k be such a distance that, if the whole mass were concentrated at that distance, the moment of inertia would not be altered: that is, let $\Sigma m \times k^2$ be Σmr^2 . Then k is what was called the *radius of gyration*. [GYRATION.]

The property which is most important in the actual determination of moments of inertia by the integral calculus is one in virtue of which the moment may be found with respect to any axis when it is known with respect to a parallel axis passing through the centre of gravity. Let PQ be an axis passing through G the centre of gravity, and let AB be another axis parallel to PQ and distant from it by GR or h . Then, whatever the moment of inertia may be when PQ is the axis, that with respect to AB is found by adding the moment of inertia of the whole system concentrated in G , or $\Sigma m \times h^2$. That is

$\Sigma mr^2 = \Sigma mp^2 + \Sigma m \times h^2$ where Σmp^2 = moment of inertia of the system with respect to PQ .

Hence it appears that of all axes parallel to a given axis the moment of inertia is least for that axis which passes through the centre of gravity; so that, *ceteris paribus*, the greatest motion is produced by a given force when the axis passes through the centre of gravity. Of all the axes which pass through the centre of gravity there are three, each at right angles to the other two, which possess remarkable properties, and are called *principal axes*. [ROTATION.]

From what has been said it may easily be supposed that the moment of inertia is as important in the consideration of rotatory motions as the rectangle in mensuration. We shall see a further use of this function in OSCILLATION, and also a practical mode of finding the moment of inertia.

MOMORDICA ELATERIUM, Wild Cucumber; called in the last edition of the 'London Pharmacopœia' by the name given to it by L. Claude Richard, *Ecbalium officinarum*, a name more appropriate than *Elaterium*, which merely means any very active purgative, while *Ecbalium* refers to the remarkable power the fruit of this plant possesses of projecting the seeds along with a thin juice out of the capsule or pepo when ripe. Hence its familiar name of "squirting cucumber." It is an annual, native of the south of Europe, but also cultivated at Mitcham, near London. The unripe pepo and the juice are officinal. A very small quantity, less than a quarter of a grain, of the dried pepo will act powerfully as a hydragogue purgative. But the juice, called extract of elaterium, yields a principle called elaterin, or momordicine, also termed elatin. This is the active principle, and is very potent. The twentieth part of a grain is often sufficient to excite active purging: rarely should more than the tenth part of a grain be given, and every precaution should be used to avoid prostration, such as not repeating the dose till an interval of one or two days, supporting the strength with beef-tea, surrounding the abdomen with a flannel belt or bandage, to be tightened after each action of the bowels, and if necessary giving at the same time, unless contra-indicated, brandy or porter. Even the juice or the vapour of it may be absorbed through the skin, and cause violent vomiting and purging.

The *Momordica operculata*, Linn., a plant in South America, one of the bitterest in the world, has, according to Dr. Hancock, similar properties.

MONACHISM (from the Greek *μόνος*, alone; whence *μονάζειν*, to live alone; and *μοναχός*, a solitary, or a monk). In this its proper and original signification of a solitary, a monk may be considered as only another name for an anchorite, or anchorite (in Greek, *ἀναχωρητής*), that is, a person who withdraws from society, a recluse; or for an eremite, corrupted into hermit (in the same way as the old and more correct *ethnick* has been corrupted into *heathen*), in Greek, *ἐρημίτης*, that is, a dweller in a desert or solitude.

The practice of retiring from the world for mortification or pious contemplation has been in use from time immemorial in the Brahminical and other religions of the East, and was known even among the Jews long before the birth of Christianity. We need mention only the instance of the prophet Elijah, to whom Roman Catholic writers indeed are fond of referring as the founder of monachism. An example of still more venerable antiquity is afforded by the Nazarites, male and female, described in the sixth chapter of the Book of Numbers, whose "vow of separation," however, lasted only for a certain fixed time.

In the earliest days of Christianity, many of the converts to the new religion, in their ambition to signalise themselves by extraordinary piety, adopted a remarkable severity of life and strictness of religious observance, whence they came to be known by the name of ascetics (in Greek *ἀσκηταί*), that is, literally, exercisers. Another name by which they are sometimes spoken of by the early ecclesiastical writers is *spoudaî* (*σπουδαῖοι*), that is, zealots. The connection of these ascetics with the description of persons afterwards called monks has been a subject of much disputation, the admirers and champions of the monastic system in general asserting the identity of the monks and ascetics, and their opponents maintaining that asceticism, as it existed in the primitive church, and monachism, as it sprung up in a later age, were two things wholly distinct. The truth appears to be that the early ascetics were certainly not universally, nor perhaps even generally, monks or solitaries; but still a separation, more or less rigid, from social life was one obvious mode of mortification and devotional abstraction, and one that was undoubtedly practised by some of the ascetics, though most probably without anything resembling the vows and other methodical restrictions which make part of monachism in its mature state. The ascetics themselves, it may be here observed, are commonly derived from the Jewish sect of the Therapeutæ, or Essenians, who inhabited the banks of the lake Mareotis, in the delta of Egypt, and who, having previously cast off much of the ancient reverence of their nation for the Mosaic law, had embraced Christianity in great numbers very soon after its promulgation. "The austere life of the Essenians," says Gibbon, "their fasts and excommunications, the community of goods, the love of celibacy, their zeal for martyrdom, and the warmth, though not the purity, of their faith, already offered a very lively image of the primitive discipline." ('Decline and Fall,' chap. 15.) And in a note, after admitting that Basnage, in his 'Histoire des Juifs,' has demonstrated, in spite of Eusebius and a crowd of modern Roman Catholics, that the Therapeutæ were neither Christians nor monks; he adds, "It still remains probable that they

ARTS AND SCI. DIV. VOL. V.

changed their name, preserved their manners, adopted some new articles of faith, and gradually became the fathers of the Egyptian ascetics." Afterwards (chap. 37), he seems distinctly to represent the ascetics as the fathers of the monks.

It is admitted on all hands that the immediate founders of monachism were two Egyptians, named Paul and Anthony. St. Jerome calls the former the author of that mode of life, the latter its illustrator—"hujus vitæ auctor Paulus, illustrator etiam Antonius." (Hieron., 'Ep. 22, ad Eustoch.', c. 16.) Paul is designated the Thebæan. An account of St. Anthony, as he is styled, and of the progress of the monastic system during his life, which extended from A.D. 251 to A.D. 356, has already been given under his name. [ANTHONY, Sr., in BIOG. DIV.] We shall only note here that the first monastic community is said to have been established at Faioum, near Aphroditopolis, in the Thebais of Egypt, about the year 305 or 306, that is, after the cessation of the persecutions which had originally driven Anthony, Paul, and others to the deserts. Strictly speaking, however, this and other monasteries appear to have been founded rather by Anthony's disciples, and in obedience to the spirit which his example had diffused, than directly under his own superintendence.

Of these disciples, the most eminent was Pachomius: if the Decian persecution and Anthony gave rise to monachism, monasteries owe their origin to Pachomius and the peaceful times of Constantine. The ancient writer of the 'Acta Pachomii' makes Anthony acknowledge this himself in the following speech to one of the disciples of Pachomius:—"When I first became a monk, there was as yet no monastery in any part of the world where one man was obliged to take care of another, but every one of the ancient monks, when the persecution was ended, exercised a monastic life by himself in private. But afterwards your father Pachomius, by the help of God, effected this." The other most celebrated early propagators of monachism are Hilarion, another disciple of Anthony, who carried the system into Palestine, about A.D. 328; St. Athanasius, bishop of Alexandria, who brought it to Rome, A.D. 340 [ATHANASIUS, in BIOG. DIV.]; Eustathius, bishop of Sebaste, or Sebastia, by whom it was soon after extended to Armenia and Paphlagonia; St. Basil, who established it in the province of Pontus, A.D. 360 [BASIL, in BIOG. DIV.]; and St. Martin, bishop of Tours, by whom it was, about A.D. 370, introduced into Gaul whence it is generally supposed to have been imported into the British Isles by Pelagius, about the beginning of the fifth century.

At first all the communities of monks followed the rule of Pachomius, and therefore they were not distinguished into various orders, as in later times, but took their names from the places where they were established, as the monks of Mount Scethis, of Tabenne, of Nitria, of Canopus, &c. But besides the monks that lived in communities, and who were called from that circumstance *Cenobitæ*, or sometimes *Synoditæ*, there were for some ages divers other species, which the ecclesiastical antiquarians have taken much pains to distinguish. Some lived, although in the same district of the wilderness, yet all in separate caves or cells, and without any association or common government, in which case the collection of hermitages was called a *Laura*, according to Epiphanius. Another sort are described by Cassian under the name of *Sarabaitæ*, and were called by the Egyptians *Remboth*, according to St. Jerome, who says that they lived two or three together, without any rule, but each after his own fashion, taking up their abode for the most part in cities and fortified stations (*castellis*). In other respects he gives a very bad account of them: although they were wont to contend with each other, he says, in extraordinary feats of fasting, yet at other times they would indulge to as much excess in riotous festivity; all things about them were affected; loose gloves (*manicæ*), puffed-out boots (*caligæ follicantes*), coarse clothes, frequent sighing, much visitation of the young women, violent inveighing against the clergy. In short, concludes Jerome, they are the pests and banes of the church. Another species of these early monks or solitaries were those called *Stylitæ*, that is, pillar saints (from *στύλος*, a pillar), the founder of whom was one Simeon, a Syrian shepherd, who having, in A.D. 408, when he was only thirteen years old, left his flocks and joined a monastic community, afterwards withdrew himself to a mountain about thirty or forty miles east from Antioch, and there, confining himself by a chain within a mandra, or circle of stones, proceeded at last to take up his residence on the top of a pillar, which was gradually raised from the height of nine to that of sixty feet. Simeon Stylites died A.D. 451, after having, it is said, existed for thirty years at the last-mentioned elevation in the air. "Habit and exercise," says Gibbon, "instructed him to maintain his dangerous situation without fear or giddiness, and successively to assume the different postures of devotion. He sometimes prayed in an erect attitude, with his outstretched arms in the form of a cross; but his most familiar practice was that of bending his meagre skeleton from the forehead to the feet; and a curious spectator, after numbering twelve hundred and forty-four repetitions, at length desisted from the endless account." This strange sort of piety, however, does not seem to have proved very contagious; among the few pillar saints, besides the contriver of the practice, whose names are recorded, the most famous are, another Simeon, styled the Younger, who is said to have occupied his airy watch-tower for sixty-eight years, and one Alypius, who lent the bishopric of Adrianople for this other sort of episcopacy, and, it is affirmed, kept singing psalms and hymns between heaven and earth,

at all hours of the day and night, for the full space of threescore years and ten, while a choir of monks and two choirs of virgins, seated on the ground below, lent the aid of their voices to swell the strain. About the beginning, or, as others think, about the middle, of the 5th century a pious individual, named Alexander, set up a new fashion of monachism at Constantinople, the professors of which received the name of *Acœmetæ* (in Greek, *ἀκομηταί*), that is, the watchers, or the sleepless, from their practice of dividing themselves into three classes, which took the performance of divine service in unbroken succession, so as to keep up a constant sound of devotion throughout the entire round of the twenty-four hours. The *Acœmetæ*, sometimes called *Studitæ*, from *Studius*, a Roman nobleman, who became one of their society, and built a famous monastery for them, which, after him, was named *Studium*, were held in great estimation, and became very numerous at Constantinople. Alongside of the *Stylitæ* may be placed another description of fantastic enthusiasts, the *Βοσκοί*, or Grazing Monks, whose whim it was to live like the beasts of the field, inhabiting no houses, and eating neither bread nor flesh, but roaming about upon the mountains, as they continued without ceasing to make the wilderness resound with their hymns and psalms, and when it was time to eat, every man, taking his knife in his hand, proceeded to cut or dig for himself a dinner of herbs from the ground. Still another sort of old monks is mentioned, under the name of *Gyrovaḡi*, the Vagabond Monks, as the epithet may be translated. St. Benedict describes these as rambling about continually from province to province, getting themselves well entertained for three or four days at every cell they came to, mere slaves to their gluttonous appetites, and in all things worse even than the *Sarabaritæ*.

From this sketch it is evident that the institution of monachism had arrived at a state of very considerable corruption both in the Eastern and the Western churches, when St. Benedict arose to reform it, in the latter, in the earlier part of the 6th century. [BENEDICTINE ORDER.] The Carthusians, Cistercians, Grandimontenses, Præmonstratenses, Cluniacs, &c., were all only so many varieties of Benedictines. The historians of monachism indeed reckon up twenty-three subdivisions of this order in all, distinguished only by such local or other specific appellations, and by some slight differences of habit and discipline. The innovations introduced by Benedict were of course longest in penetrating to the more remote corners of Christendom; and perhaps in no other part of Europe were they so long in being generally received as in the British Islands. Bede and others denominate the system which prevailed among the British monks before the arrival of St. Augustine in 597, the apostolic discipline; but it was probably merely the ancient rule of Pachomius. It is even disputed whether St. Augustine brought over with him the rule of St. Benedict; and at all events it is tolerably clear that the rule was not universally established in the British churches till its observance was enforced by St. Dunstan and his friend Oswald, in the reign of Edgar, after the middle of the 10th century.

Meanwhile in the Eastern church also monasteries and nunneries had been made the subject of legal regulation by a constitution of Justinian (Nov. 5), addressed to Epiphanius, the archbishop of Constantinople and œcumenic patriarch, in the consulship of Belisarius, A.D. 535. Persons were not permitted to assume the monastic habit till after a three years' probation, and the abbots (*ἡγουμένοι*) were required, during this time, to examine well into their life, conversation, and fitness for the monastic profession. On being approved, the candidates assumed the dress and tonsure. Both free persons and slaves were alike admissible into monasteries, and were received on the same footing in all respects. It seems that a man could leave his monastery and enter the world again, though it was considered sinful; but as all the property which he had not disposed of before entering the monastery (subject to some provisions for his wife or children, if he had any) became the property of the monastery on his entering it, if he chose to leave it he could not take with him or recover any part of his property. Celibacy and chastity were required of the monks, though at this time marriage was permitted to certain clerical persons, as singers and readers. Further regulations on the life of monks and nuns are contained in the 134th Novel.

In the earliest age of the monastic system, the monks were left at liberty as to many things which were afterwards made the subject of strict regulation by the laws either of the state or the church. St. Athanasius, in one of his epistles, speaks of bishops that fast, and monks that eat and drink; bishops that drink no wine, and monks that do; bishops that are not married, and many monks that are the fathers of children. Originally, too, monks were all laymen; and, although it gradually became more and more the common practice for them to take holy orders, it was not till the year 1311 that it was made obligatory upon them to do so by Pope Clement V. Nor was any vow of celibacy or any other particular vow formally taken by the earliest monks on their admission. It appears even that it was not unusual for persons to embrace the monastic life with the intention of only continuing monks for a few years, and for those who had spent some time in a monastery actually to return to the world.

The word nun, in Greek *Novis*, in Latin *Nonna*, is said to be of Egyptian origin, and to signify a virgin. Another account is, that the original meaning of the Latin *nonna*, *nonnana*, or *nonnanis*, was a penitent. The Italians still use *nonno* and *nonna* for a grandfather

and grandmother. Cyprian and Tertullian, in the latter part of the 3rd century, make mention of virgins dedicating themselves to Christ. Such a practice was indeed a natural mode of self-sacrifice, which had been familiar to all religions. Some of these ecclesiastical or canonical virgins, as they were called, appear already to have formed themselves into communities, similar to those of the monks; but others continued to reside in their fathers' houses. The progress of female monachism, however, from the rudeness and laxity of the first form of the institution, to the strict regulation which characterised its maturity, moved on side by side with that of male monachism.

Monasteries are called by the Greek fathers not only *Μοναστήρια* and *Μοναί*, but also sometimes *σεμνεῖα*, that is, holy places; *ἡγουμενεία*, the residences of the abbots, styled *ἡγουμένοι*, or chiefs; *μάνδραι*, inclosures; and *φροντιστήσια*, places of reflection or meditation, that being one of the purposes to which they were very early applied.

The three vows of chastity, poverty, and obedience, are taken by all monks and nuns at their admission. All, both male and female, likewise receive the tonsure, like all the ecclesiastics of the Romish church. In all the orders the candidate for admission must first undergo a noviciate, which varies from one to three years. The age at which novices may make profession differs in different countries; but the rule laid down by the council of Trent only requires that the party, whether male or female, should be sixteen. It is scarcely necessary to add, that in the modern constitution of monachism, the vows and status of a professed person, as indeed of all ecclesiastics, are by the law of the Roman church for life and indelible.

The greatest revolution by which the history of monachism has been marked since the establishment of the rule of St. Benedict, was the rise, in the beginning of the 13th century, of the Mendicant Friars. Of these an account has been given under the word *FRIARS*; and further particulars will be found under the names of the several orders.

The general dissolution of monastic establishments was one of the first consequences of the Reformation in our own and all other countries that separated from the Romish church. There are however a few Protestant monastic establishments in some parts of Germany. Even in some Roman Catholic countries, especially in Germany and France, the number of these establishments has been greatly reduced within the last fifty or sixty years, and the wealth and power of those of them that still exist most materially curtailed. The reform of the German monasteries was begun by the emperor Joseph II.; those of France were all swept away at the commencement of the first Revolution; but some of them were set up again, though with diminished splendour, after the restoration of the Bourbons. Since the relaxation of the penal laws, several Roman Catholic nunneries have been erected in England and Scotland, as well as in Ireland. Monks and nuns of all descriptions still swarm in Italy, and in the countries of South America lately subject to the Spanish and Portuguese crowns; in Spain and Portugal monasteries were suppressed by the Cortes, during the war against Bonaparte: but many of them have been since restored, though much of their property has been sold and applied to national purposes. Even in modern times we still hear occasionally of the institution of a new order of monks. One, called the Congregation of the Blessed Virgin Mary, was established by the late Pope Leo XII., in 1826.

MONARCHY, from the Greek *μοναρχία*, a word compounded of *μονός*, "alone," and the element *ἀρχή*, "govern," and signifying the "government of a single person." The word *monarchy* is properly applied to the government of a political community in which one person exercises the sovereign power. [SOVEREIGNTY.] In such cases, and in such cases alone, the government is properly styled a monarchy, and the supreme ruler is properly styled a monarch. Examples of monarchy, properly so called, are afforded by many Oriental governments, both in ancient and modern times, by the governments of France and Spain in the last century, and the existing governments of Russia, Austria, and France.

But since monarchs have in many cases borne the honorary title of *βασιλεὺς*, *rex*, *re*, *roi*, *könig*, or *king*, and since persons so styled have, in many states not monarchical, held the highest rank in the government, and derived that rank by inheritance, governments presided over by a person bearing one of the titles just mentioned have usually been called *monarchies*.

The name *monarchy* is however incorrectly applied to a government, unless the king (or person bearing the equivalent title) possesses the entire sovereign power; as was the case with the king of Persia (whom the Greeks called "the great king," or simply "the king"), and in more recent times with king Louis XIV., called by his contemporaries the *Grand Monarque*.

Now a king does not necessarily possess the entire sovereign power; in other words, he is not necessarily a monarch. Thus the king has shared the sovereign power either with a class of nobles, as in the early Greek states (Müller's 'Dorians,' b. iii., c. 1), or with a popular body, as in the Roman kingdom, in the feudal kingdoms of the middle ages, and in Hungary till the 18th century, and modern England, Holland, Belgium and Sardinia. The appellation of *monarch* properly implies the possession of the entire sovereign power by the person to whom it is affixed. The title of *king*, on the other hand, does not imply that the king possesses the entire sovereign power. In a state where the

king once was a monarch, the kingly office may cease to confer the undivided sovereignty; and it may even dwindle into complete insignificance, and become a merely honorary dignity, as was the case with the *ἀρχὴν βασιλεὺς* at Athens, and the *rex sacrificulus* at Rome. (Creuzer's 'Abriss der Römischen Antiquitäten,' § 133.)

In Sparta there was a double line of hereditary kings, who shared the sovereign power with some other magistrates and an assembly of citizens. The government of Sparta has usually been termed a republic, but some ancient writers have called it monarchical, on account of its kings; and Polybius applies the same epithet to the Roman republic, on account of its two consuls. ('Philological Museum,' vol. ii., p. 49, 57.)

States which were at one time governed by kings possessing the entire sovereign power, and in which the king has subsequently been compelled to share the sovereign power with a popular body, are usually styled *mixed monarchies* or *limited monarchies*. These expressions mean that the person invested with the kingly office, having once been a monarch, is so no longer; and they may be compared with such expressions as *ῥᾶς ἀναεῖς*, which occur in the Greek poets.

Governments are divided into *monarchies* and *republics*; and therefore all governments which are not monarchies are republics. As we have already stated, a monarchy is a government in which one person possesses the entire sovereign power; and consequently a republic is a government in which the sovereign power is shared between several persons. [REPUBLIC.] These definitions of *monarchy* and *republic* however do not agree with existing usage; according to which, the popular though royal governments of England and Belgium, for example, are monarchies (namely, *mixed* or *limited* monarchies), not republics.

The popular usage of the terms in question, to which we have adverted, is mainly owing to three causes. 1. Kings not possessing the entire sovereign power have in many cases succeeded kings who did possess the entire sovereign power; in other words, kings not monarchs have in many cases succeeded kings who were monarchs. 2. Both in royal monarchies and in royal republics, the crown or regal title usually descends by inheritance. 3. Kings who are not monarchs usually affect the state of monarchs properly so called; they intermarry only with persons of monarchical or royal blood, and refuse to intermarry with persons of an inferior degree.

Governments such as those of England and Belgium are included by popular usage, together with republics, in the term "free or constitutional governments," as distinguished from pure monarchies, absolute monarchies, or despotisms.

According to the existing phraseology therefore, the use of the two terms in question is as follows:—

Monarchies are of two sorts, namely, *first*, pure, absolute, or unlimited monarchies, that is, monarchies properly so called; and *secondly*, limited, mixed, or constitutional monarchies, or monarchies improperly so called, that is, republics presided over by a king or kingly governments where the king is not sovereign.

Republics are states in which several persons share the sovereign power, and in which the person at the head of the governing body does not bear the title of king. Accordingly, Holland with a stadtholder, Venice with a doge, and England with a protector, are called republics, not monarchies. If the head of the Venetian aristocracy had been styled king instead of doge, and if his office had descended by inheritance instead of being conferred by election, Venice would have been called a monarchy, and not a republic. The only exception to this usage of which we are aware occurs in the case of Sparta, which is commonly called a republic, and not a monarchy, although it had hereditary kings. The reason of this exception probably is, that there being two lines of kings at Sparta, it was thought too gross an inaccuracy to call its government monarchical; though its government would have been called monarchical, if there had been only one king, in spite of the narrow powers which that king might have possessed.

MONASTERY. [MONACHISM.]

MONESIN. A non-azotised organic substance resembling saponin, found in the bark of the *Chrysophyllum glycyphleum*.

MONEY is the medium of exchange by which the value of commodities is estimated, and is at once the representative and equivalent of such value.

Barter is naturally the first form in which any commerce is carried on. A man having produced or obtained more of any article than he requires for his own use, exchanges a part of it for some other article which he desires to possess. But this simple form of exchange is adapted to a rude state of society only, where the objects of exchange are not numerous, and where their value has not been ascertained with precision. As soon as the relations of civilised life are established in a community, some medium of exchange becomes necessary. Objects of every variety are bought and sold, the production of which requires various amounts of labour; these at different times are relatively abundant or scarce; labour is bargained for as well as its products: and at length the exchangeable value of things, in relation to each other, becomes defined, and needs some common standard or measure by which it may be expressed or known. It is not sufficient to know that a given quantity of corn will exchange for a given quantity of a man's labour, for their relative value is not always the same; but if a standard is established by which each can be measured, their relative value can

always be ascertained as well as their positive value, independently of each other.

As a measure of value only money is thus a most important auxiliary of commerce. One commodity from its nature must be measured by its weight, another by its length, a third by its cubic contents, others by their number. The diversity of their nature, therefore, makes it impossible to apply one description of measure to their several quantities; but the value of each may be measured by one standard common to all. Until such a standard has been agreed upon, the difficulties of any extensive commerce are incalculable. One man may have nothing but corn to offer for other commodities, the owners of which may not have ascertained the quantity of corn which would be equivalent for their respective goods. To effect an exchange these parties would either have to guess what quantity of each kind of goods might justly be exchanged for one another, or would be guided by their own experience in their particular trades. Whenever they wanted a new commodity their experience would fail them, and they must guess once more. But with money all becomes easy; each man affixes a price to his own commodities, and even if barter should continue to be the form in which exchanges are effected, every bargain could be made with the utmost simplicity: for commodities of every description would have a denomination of value affixed to them, common to all and understood by everybody.

But however great may be the importance of money as a measure of value in facilitating the exchange of commodities, it is infinitely more important in another character. In order to exchange his goods it is not sufficient that a man should be able to measure their value, but he must also be able to find others who, having a different description of goods to offer as an equivalent, are willing to accept his goods in exchange, in such quantities as he wishes to dispose of. Not to enlarge, however, upon the obvious difficulties of barter, which have been sufficiently indicated under BARTER, it will suffice to observe that all its difficulties are removed if some one commodity can be discovered which represents a certain amount of labour, and which all persons agree to accept as an equivalent for the products of their own industry. If such a commodity be found, it is no longer necessary for men to exchange their goods directly with each other; they have a medium of exchange, which they can obtain for their own goods, and with which they can purchase the goods of others. This medium, whatever it may be, is Money.

When money has assumed the character of a medium of exchange and equivalent of value, the cumbrous mechanism of barter gives place to commerce. But what must be the qualities of an article which all men are willing to accept for the products of their own labour? It is now no longer like a weight or measure, the mere instrument for assessing the value of commodities; but, to use the words of Locke, "it is the thing bargained for as well as the measure of the bargain." A bargain is complete when money has been paid for goods; it has no reference to the price of other goods, nor to any circumstance whatever. One man parts with his goods, the other pays his money as an absolute equivalent. But though money as a medium of exchange thus differs from money as a mere standard of value, yet in both characters it should possess, if it be possible, one quality above all others—an invariable equality of value at all times and under all circumstances. As a measure of value it is as essential that it should always be the same, as that a yard should always be of the same length. And unless, as a medium of exchange, its value be always the same, all bargains are disturbed. He who gives his labour or his goods to another in exchange for a delusive denomination of value instead of for a full equivalent which he expects to receive, is as much defrauded as one who should bargain for a yard of cloth and receive short measure.

But however desirable may be the invariableness of money, complete uniformity of value is an impossibility. There is no such thing as absolute value. All descriptions of measures correspond with absolute qualities, such as length, weight, and number, and may be invariable. But as value is a relative and not an absolute quality, it can have no invariable measure or constant representative. The value of all commodities is continually changing; some more and some less than others. Their real value depends upon the quantity of labour expended upon them; but temporary variations in their exchangeable value are caused by abundance or scarcity—by the relations which subsist between supply and demand. No commodity yet discovered is exempt from the laws which affect all others. If precisely the same quantity of labour were required for a long series of years to produce equal quantities of any commodity, its real value would remain unchanged; but if it were at the same time an object of demand amongst men, variations in the proportion between its supply and the demand for it would affect its exchangeable value. It follows therefore, that to be an invariable standard, money must always be produced by the same amount of labour, and in such quantities as shall constantly bear the same proportion to the demand for it.

But even if any description of money could be invented which possessed these extraordinary qualities, the value of all other articles would still be variable, and thus its representative character would be disturbed. At one time, for example, a given denomination of money will represent a certain number of bushels of wheat; at another time the same money, unchanged in real value or demand, will represent a much greater number. Every application of machinery, every addition to the skill and experience of mankind, facilitates production, and by

saving labour reduces the real value of commodities. Their value is also liable to temporary depreciation from other causes, from too abundant a supply, or from an insufficient demand. But if money maintain the same value, in relation to itself, notwithstanding the diminished value of other articles, its proportionate value is practically increasing.

In all ages of the world, and in nearly all countries, metals seem to have been used, as it were by common consent, to serve the purposes of money. It is true that other articles have also been used, and still are used, such as paper in highly civilised countries, and cowrie shells in the less civilised parts of Africa; but in all some portion of the currency has been and is composed of metals. We read of metals amongst the Jews, the Chinese, the Egyptians, the Persians, the Greeks, the Romans. In the earliest annals of commerce they are spoken of as objects of value and of exchange; and wherever commerce is carried on they are still used as money. But as they were introduced for this purpose in very remote times, it is not probable that they were selected because their value was supposed to be less variable than that of other commodities. More than two thousand years ago, indeed, Aristotle saw clearly (but what did he not see clearly?*) that the principal use of metallic money was that its value was less fluctuating than that of most other substances ('Ethic. Nicom.' v. 5). But however clearly this great philosopher may have observed the true character of money, many ages after the circulation of metals, those who first used them were men engaged in common barter, who considered their own convenience and security without reference to any general objects of public utility. They must have used metals not as a standard of value but as an article of exchange, which facilitated their barter. All metals are of great utility and have always been sought with eagerness for various purposes of use and ornament: but gold and silver are especial objects of desire. Their comparative scarcity, the difficulty and labour of procuring them, their extraordinary beauty, their singular purity, their adaptation to purposes of art, of luxury, and display; their durability and compactness; must all have contributed to render them most suitable objects of exchange. They were easily conveyed from place to place; a small quantity would obtain large supplies of other articles; they were certain to find a market; none would refuse to accept articles in payment which they could immediately transfer to others: and thus gold and silver naturally became articles of commerce, readily exchangeable for all other articles, before they were circulated as money, and were acknowledged as such by law and custom.

The transition of the precious metals from the condition of mere articles of exchange, amongst many others, to that of a recognised standard of value by which the worth of all other articles was estimated, was very natural. Merchants carrying their wares to a distant market would soon find it necessary to calculate the quantity of gold and silver which they could obtain, rather than the uncertain quantities and bulk of other commodities. They would not know what articles it would be prudent to buy until they reached the market and examined their quality and prices: but a little experience would enable them to predict the quantity of gold and silver which would be an equivalent for their own merchandise. Merchants from different parts of the world, meeting one another in the same markets, and finding the convenience of assessing the value of their goods in gold and silver, would begin to offer them for certain quantities of those metals, instead of engaging, more directly, in bartering one description of goods for another; and thus, by the ordinary course of trade, without any law or binding custom, the precious metals would become the measure of value and the medium of exchange.

But when gold and silver had attained this position in commerce, they were not the less objects of barter; nor were they distinguishable in character from any other articles of exchange. They were weighed, and being of the required fineness, a given weight was known as a denomination of value, but in the same manner only as the value of a bushel of wheat may be known. In the earliest ages gold and silver seem to have been universally exchanged in bars, and valued by weight and fineness only. The same custom exists at the present day in China. There is no silver coinage, but the smallest payments, if not made in the copper *tchen*, are effected by exchanging bits of silver, whose weight is ascertained by a little ivory balance on the principle of the steelyard." (Davis's 'China,' c. 22.)

Notwithstanding the ease with which gold and silver are divided into the smallest portions, each of which is of the same intrinsic purity and value as the others, the trouble of weighing each piece, and the difficulty of assaying it in order to detect alloys of baser metals, render these metals in bars, or other unfashioned forms, ex-

* Many important principles of political economy, the discovery of which is attributed to Adam Smith and other modern writers, may be found in the works of Aristotle, expressed with wonderful precision and clearness. Mr. McCulloch, for example, refers to Locke as the first who laid it down that labour is the source of value; but the same principle was affirmed by Aristotle in more than one part of his works, and more accurately than by Locke ('Ethic. Nicom.' v. 5). Again, he perceived, perhaps as distinctly as any other writer, the distinction between productive and unproductive labour ('Metaph.' ix. 8). As another example we would refer to his account of the origin of barter, its development into commerce, and the connection of the latter with the use of money ('Pol.' i. 6). And, lastly, any economist must be struck with his clear perception of the relations between a division of employments and the exchange of the products of labour (Ib. ii. 2).

tremely imperfect instruments of exchange, especially when they are used in small quantities. However accurately they may be weighed, it requires considerable skill and labour to assay them, which in small pieces would scarcely be repaid. Even in large quantities the difficulty of assaying their fineness, in countries which have made considerable advances in the arts, is greater than might be expected. To obviate this difficulty coinage was introduced, by which portions of gold, silver, copper, and other metals have been impressed with distinctive marks, denoting their character, and have become current under certain denominations, according to their respective weight, fineness, and value. These coins have always been issued by the government of each country as a guarantee of their genuineness; and the counterfeiting of them has been punished as a serious offence against the state.

In rich countries these three metals of gold, silver, and copper, or of a mixed metal, such as bronze, are very convenient substances for the manufacture of coins, on account of the differences in their relative value. Gold coins, containing a high value in small compass, are convenient for large payments, silver coins for smaller payments, and copper or bronze coins for those of the lowest value; while all the larger coins are multiples of the smaller. These several descriptions of coin serve the ordinary purposes of trade sufficiently well: they are universally received as money within the country in which they circulate, and the principal part of all payments of moderate amount is made in them. But payments of large amounts cannot conveniently be made in coins of any metal; and in this and other countries paper money and various forms of credit have been used as substitutes. Of these we shall speak presently; but it will first be necessary to consider the suitability of gold and silver coins as standards of value.

Coins made of these metals are not exempt from the laws which govern the prices of other commodities. They have accordingly varied in their own value in successive periods, and are at no time secure from variation. In the 16th century new mines of extraordinary richness were opened in America, from which a large amount of the precious metals was poured into Europe; this gave a great stimulus to commerce and industry, and a material change took place in the relative prices of these metals, and other commodities.

The discovery of the gold deposits in California has brought such considerations into the class of debateable questions in our own day. The distinguished political economist, M. Michel Chevalier, in his lectures before the College of France, published in 1850, predicted that if Russia and California continued to produce gold at the rate they were then doing, the value of gold would be ultimately reduced by five sixths, or even nine-tenths. He admits, however, that the fall, though rapid at first, would be greatly retarded by the adaptability and greater beauty of gold for purposes of ornament or use, for which silver is now used. This opinion, slightly modified, is repeated in his work 'On the probable Fall in the Value of Gold,' translated in 1859 by Mr. Cobden; and he attributes the little effect hitherto produced, even with the addition of the immense quantity imported from Australia, to the absorption of a large proportion of it by France in exchange for her silver. In these predictions, however, he is thought by some to overlook many material facts, the influence of which the experience of twenty years has in a great degree substantiated. The addition of gold or silver forms an addition to the world's capital, and this capital forms a fresh labour fund; such additions therefore give a great stimulus to increased industry, and the wages for this industry require and absorb a large though an indefinite quantity of the precious metals. M. Chevalier saw this to some extent, for he says ('La Monnaie,' p. 473), "that such an increase as was then taking place would compel England, for the purposes of her commerce, to increase ninefold the amount of her coined gold." The anticipated fall has not followed; the general increase of manufacturing industry, the exports from England in a few years mounting from 50,000,000*l.* to 130,000,000*l.*, has necessitated a corresponding increase in the sum distributed as wages, which has been accompanied by a great increase of imported articles for home consumption by the classes so benefited; the import of tea, for instance, increasing from 40,000,000 *lbs.* in 1838, to 75,000,000 *lbs.* in 1858. This again has occasioned a reaction not contemplated by M. Chevalier. China takes little except silver in exchange for her tea; the East Indies also require silver for their commodities, and in this way from 15,000,000*l.* to 20,000,000*l.* in silver are abstracted from Europe, which deficiency must be filled either with gold or silver from the various mines in work. Thus in the year 1859, the total quantity of gold and silver bullion imported into the United Kingdom was valued at 37,070,156*l.*; of which 20,370,901*l.* from the United States, Australia, and Russia, was probably gold; and 7,302,308*l.* from France, and 5,123,982*l.* from Mexico and South America, will probably represent the silver. The exportations amounted in value to 35,688,803*l.*, of which 10,384,371*l.* went to France, no doubt in gold to replace her abstracted silver; and 16,616,531*l.* to Egypt, for transmission to India and China, nearly all of which must have been in silver. The influx of the precious metals (for the produce of silver continues to be large) has had, as yet, little visible effect on the prices of commodities in general, and none whatever in the relative values of the two metals; at least none beyond the slight variations occasioned by the wants of commerce for the one or the other. Articles of consumption for food or clothing are not higher in price than before the

gold discoveries. But it is impossible distinctly to assign the rise or the fall in prices to the influx of the precious metals, during a period when the operation of our new commercial system has unquestionably placed, not only agricultural produce, but articles of luxury, more within the reach of the majority of consumers. There may have been a continuous fall in the price of the necessities of life under a large additional supply of Australian gold; and there may also have been a continuous rise, such as that of meat, from the greater stimulus to industry demanding more labourers, and therefore raising the rate of wages. Many variations in the price of products manifestly depend on their own scarcity or abundance, and not merely on the increase of gold. It is satisfactory to know that since the time of the Australian gold discoveries, the rise in the wages for labour has been more marked than the average rise in the price of commodities, enabling the labouring population not only to increase, but to consume more, and of a better quality, than they could previously, thus maintaining and extending the demand for, and the capability of employing, almost any fresh amount of the precious metals, whether silver or gold.

There is a difficulty in deciding the question whether, or to what extent, the price of gold fell on the influx of gold at the end of the 16th century or on the Californian and Australian discoveries in the middle of the 19th. By the Windsor tables, the price of wheat in England averaged about 34s. per quarter, from 1606 to 1625, sometimes however reaching as high as 58s. per quarter and sometimes sinking as low as 30s. It subsequently ranged, under Charles I., from 40s. to 44s. per quarter; a sum not widely different from the present prices. Wheat, taken in decennial averages from 1660 to 1860, has averaged only 49s. per quarter. But the rate of labour has permanently increased nearly cent. per cent., while at the same time many articles of luxury and convenience have become cheaper through the improvements in the means of production. These variations, like all of similar character, evidently depended on the abundance or the scarcity of harvests, unrelieved by an extended foreign commerce. Except in long averages, the prices of articles of consumption afford no proof of any alteration in the value of money. Potatoes or meal—oat, rye, or wheat meal—in Ireland, during the time of the potato-rot, or boots at the Australian diggings, may have fetched fabulous prices; but it is at once seen in these cases, that it is the exceptional circumstances, and not any real alteration in value, that has produced the difference. The general effect of an influx of the precious metals appears to have been to stimulate industry; this industry, represented largely by manual labour, had to be paid for; this, in its turn, enabled a much larger proportion of the population to consume more food, and of a better quality than previously, and rye-, oat-, and barley-bread, disappeared in England from the consumption even of the paupers.

Gold, after all, only represents labour. On the discovery of the riches of Peru and Mexico, they were found already accumulated, and were merely transferred to new possessors, without labour and with little risk. In the more recent discoveries, the produce has been the result of labour. This labour has been looked at as wonderfully profitable. In a few lucky instances it may have been so, but on the average it is doubtful whether the labour has not been sufficient to maintain the value of the gold; for if the labourer received high pay, he had to pay exorbitantly for the necessary means of his maintenance; and those who supplied him with those means, though they charged high, had to convey them to him at an immense expense, and under great difficulties, so that no great excess of profit was made by any one beyond what is gained by the early possession of a good market.

M. Chevalier predicts that the labourer will be a great ultimate sufferer from the continued influx of gold, and its consequent depreciation; because, he says, the price of labour, though it follows the price of articles of consumption, does so very slowly; and therefore, as the value of gold descends, and the comparative value of all other articles rises, he will never be able to maintain his relative position. This is in some degree to appear to overlook a truth which so experienced an economist as M. Chevalier cannot really have overlooked, that there is no absolute relation between the wages of labour and the price of commodities. If the influx of gold gives a stimulus to home industry—if the gold-digger of Australia becomes a new and profitable customer to the manufacturer of Britain—the increase in the demand for labourers causes a rise in wages which may be equal to, or even exceed, a rise in the price of commodities. But further—we must take into account the difference between the precious metals and articles of consumption. If a favourable season renders corn and cattle abundant, the increase of so much capital gives means for enlarged expenditure, promotes industry, tends to raise the rate of wages by the extended demand for labour, and so far resembles the effect produced by an increased supply of gold. But a falling off in the supply of articles of consumption has no similarity with that of gold. A dearth not only suddenly raises the price, in a proportion far exceeding the actual deficiency, but by concentrating expenditure upon articles of necessity, checks or almost entirely stops industry. It is then the labourer suffers. What he needs has attained an exorbitant value, while what he has to offer in exchange, his labour, has lost its value from the want of means of employing it profitably. But no such effect could possibly follow from the total suspension for years of any

supply of gold. There might be less stimulus to industry, but the gold which was sufficient before the supply stopped, would remain to be still employed in exchange; and this would continue unaltered for years. It is this property which renders gold so peculiarly the best standard of value.

Contemplating the ultimate depreciation of gold, the writer of the article in the 'Edinburgh Review' recommends the adoption of a system of corn averages. He proves very satisfactorily that any considerable depreciation in the value of gold, as money, would press with great and undue severity on all persons with fixed incomes, and on the labourer. The adoption of his suggestion, we believe, would rather increase than mitigate the evil; for depending on the seasons, there are few things necessarily subject, from the variation in both quantity and quality in successive years, to such large and sudden alterations as the price of corn. In the year ending Michaelmas, 1853, after the supply of gold had been much increased, the average price of wheat was 45s. 8d. per quarter; in the following year it was 73s. 1d.; and it continued as high, or somewhat higher, for the following two years; but in 1858, with all the fresh importations of gold, the average was only 46s. per quarter, and in 1859 only 43s.

As M. Chevalier and the Reviewer admit that in speaking of relative values, it is difficult to decide which rises and which falls, should we not select that article which suffers the least physical change, and is least dependent on the seasons? Gold is peculiarly such an article. Abstractedly, gold may be less valuable than iron, but from its beauty, and the difficulty and labour of procuring it, it has been accepted by all mankind as the representative of value. From its indestructibility, the amount remains unwasted, which is the case with few other articles; from its portability and intrinsic value it can be secured with less danger, and used with greater convenience, than most other materials; its value is therefore more likely to be fixed than anything else.

Both gold and silver are alike subject to the general law of demand and supply, and are therefore imperfect standards of value. If one be the standard independently of the other, it is liable to change in itself, and also in its relation to other commodities: if both be adopted as standards at the same time, they will not only each vary in themselves, and in relation to other commodities, but they will vary also in regard to each other. And thus another element of uncertainty is introduced into the coinage, which becomes still more imperfect as a standard.

But it is not customary for the state to allow coins to fluctuate in their legal value according to the circumstances which determine the market prices of gold and silver. Coinage does not merely authenticate the weight and fineness of a piece of metal, leaving it to find its own level in exchange for other commodities; but it attaches to it a definite value, by fixing the standard price of the metal as well as the weight and fineness of the coin. The object of this regulation is to maintain a greater equality in the standard; and as regards small fluctuations in the value of the precious metals, it will generally have that effect, at any rate for the country for which they were coined. But if any considerable disproportion should arise between the standard price of bullion and the market price, no such regulation can prevent a practical change in the standard. If the market price should become considerably higher than the standard price, the coins would be melted down for the sake of the profit arising from the difference. If it should become considerably lower for any length of time, the value of the coins, though nominally unchanged, would in fact be depreciated; for they would exchange for a less quantity of other commodities than they exchanged for before. And thus a currency composed exclusively of metals cannot be made an accurate standard of value by any expedients of law.

We may here remark, however, that a seignorage, or charge by government to cover the expenses of coinage, acts as a protection, within certain limits, against the melting of coins, because unless their value be depreciated by over-issue, the whole charge will be added to their value as coins, and will be lost when they are melted. For this amongst other reasons a seignorage should always be charged by the state.

There is yet another imperfection in coins as standards of value. Notwithstanding their natural durability, they are subject to continual wear, and must be gradually diminished in weight. They are also exposed to the fraudulent experiments of men whose trade it is to rob them of a portion of their weight by artificial wear. The value of coins is therefore certain to be continually depreciated by loss of weight, apart from any other causes of variation.

From all these circumstances it is evident that gold and silver coins have qualities inherent in them which render them necessarily imperfect standards of value, with whatever care and skill they may be regulated. But, in addition to these natural causes of imperfection, others have been artificially produced by erroneous or dishonest political expedients. There is no country perhaps in which the coinage has never been debased by the government. Debasement of coins was formerly a common artifice for increasing the revenue of states, and it has been effected in three different ways:—1. By diminishing the quantity of metal, of the standard fineness, in coins of a given denomination; 2. By raising their nominal value and ordaining that they shall pass current at a higher rate; and, 3. By debasing the metal itself, that is, by leaving the coin of the same weight as before, but

reducing the quantity of pure metal and increasing the quantity of alloy. In all these ways have the coins of England been debased at different periods of our history; and to so great an extent were they debased by successive kings, that from the Conquest to the reign of Queen Elizabeth the total debasements of the silver coins have been estimated at 65 per cent. (Lord Liverpool, 'On Coins.') By expedients of an opposite character the standard of coins may be artificially raised; and the result of measures connected with the coinage of this country was, that in a period of 115 years, from the 1st James I. to the 1st George I., the value of gold coins, as compared with silver coins, was raised 39 per cent. (*Ibid.*) No further examples are needed to prove the inconstancy of coins as a standard, when they form the sole currency of a country.

But notwithstanding these imperfections, the convenience of gold or silver coinage, as money, has led to the universal adoption of one or the other, or of both conjointly, as the standard of value. The objections to a double standard have already been noticed, but throughout a long period of the history of this country we find gold and silver prevailing equally as standards. There appears to have been no public coinage of gold at the royal mints prior to the 41st Henry III. The gold pennies coined at that time were expressly declared not to be a legal tender, and never obtained a very general circulation. Silver was then the universal medium of exchange, and the people were unaccustomed to the use of gold as money: but as their commerce and riches increased, gold naturally became more convenient for large payments. The results of this progress became apparent in the reign of Edward III., who established a general circulation of gold coins, which, though partially introduced nearly a hundred years before, by Henry III., had not been continued by his successors. From this time gold and silver coins circulated together, and were both legal tenders. To what an extent their relative value varied at different periods, has already been noticed; but they were equally recognised by law as authorised standards of value in all payments whatever, until the year 1774, when it was declared by statute (14 Geo. III. c. 42) that, in future, silver coins should not be a legal tender in payment of any sum exceeding 25*l.*, except according to their value by weight, at the rate of 5*s.* 2*d.* an ounce. This was a temporary law, but was continued by several statutes until the year 1816, when the legal tender of silver coins was further restricted to payments not exceeding forty shillings (56 Geo. III. c. 68). And thus, as all large payments were made and calculated in gold coins, gold became the sole standard of value, so far as coinage alone was the real medium of exchange.

The expediency of adopting gold as the standard instead of silver, has been a question of much controversy amongst the highest authorities upon monetary affairs. It was the opinion of Locke, of Harris, and Sir William Petty (all great authorities), that silver was the general money of England, and the measure of value in its commercial dealings with other countries. Its general adoption for such purposes was urged as a proof of its superiority as money over gold; and of this opinion are some writers of high authority at the present day. On the other hand it has been argued, that the metal of which the chief medium of exchange is fabricated, should have reference to the wealth and commerce of the country for which it is intended; that copper or silver coins of the lowest denominations suffice for the convenience of a very poor country; but that as a country advances in wealth its commercial transactions are more costly, and require coins of corresponding value. As a matter of convenience this is undoubtedly true. Gold is the standard in England; silver is the standard in Holland and other countries; France has a double standard, silver and gold; and the comparative facility for effecting large payments in the current coins of those countries can admit of little doubt. Habit will familiarise the use of silver, and render a people insensible to its inconvenience; but it is certain that in England fifty sovereigns can be carried about in a man's waistcoat pocket, while in France the value of that sum in silver would weigh about 15 lbs. troy. The fixed price of gold, of the coinage standard of 22 carats fine to 2 of alloy, at the Mint or Bank of England is at the rate of 3*l.* 17*s.* 9*d.* per oz. There is no fixed price for silver; but the average on a long number of years is almost exactly 5*s.* The Mint coins one ounce of silver (Mint standard) into 5*s.* 6*d.*, and obtains therefore 4*d.* or 6*d.* on the ounce profit for coinage. For gold coinage it only charges a small seigniorage; the Bank of England, by an arrangement with the Government, receiving gold at the fixed rate of 3*l.* 17*s.* 9*d.* per ounce (Mint standard), and returning it coined at the rate of 3*l.* 17*s.* 10½*d.* per ounce. The price of gold is therefore kept at a standard deviating only by 1½*d.* per ounce.

But the convenience of coin for a certain class of payments is a question quite distinct from that of its fitness for a standard of value. It is not necessary to exclude gold from the coinage because it is not adopted as the standard; it may be circulated as freely as the people desire to use it, while, instead of being the legal standard, its value may be calculated in silver. If silver be the standard, a large gold coinage may circulate at the same time for the convenience of larger payments, just as silver circulates for small payments where gold is the standard. In either case, however, that metal which is chosen by the state as the lawful standard governs all calculations and bargains, while the other metal merely conforms to its standard, and is subsidiary to it. But even if the relative convenience of gold or silver as a standard

were the sole question, it could not be determined by the modes of effecting large payments only. All payments are calculated as easily in the coins of one metal as of another, in whatever form they may be actually effected. But by far the greater number of bargains are made for articles of small value. It is in silver and copper that the consumption of all commodities is mainly paid for. The wages of the country are paid and expended in that form; and in that form the prices of nearly all the ordinary articles of daily use are calculated.

The fitness of a standard however cannot be determined solely by considerations of convenience; for we must chiefly regard its intrinsic qualities as a permanent measure of value. How shall uniformity of value be maintained as far as practicable in the money of a country? is the main question to be determined; and not, Which is the most convenient form in which to make bargains? In what medium shall the whole property of the country be valued, from one year to another. By what standard shall the relative value of all things be compared? How shall fluctuations be restrained in the value of this standard itself? These are the questions to be answered.

In favour of gold as a standard it is argued that being less extensively used for plate and other manufactures, it is less an article of commerce than silver, and is confined more specially to the purposes of money. On the other hand, it is contended that gold is used in large quantities for jewellery, watches, and decorative purposes, and that being a more costly material, its consumption in this affects its quantity and value to a greater extent than the use of plate affects the price of silver. And in this argument there is much weight, for it is estimated that the quantity of gold compared with the quantity of silver is as 1 to 50; and their relative value is as 1 to 15. (See 'Bullion Report,' 1810. Allen's Evidence.) Yet in a long series of years the relative prices of the two metals have not materially varied; but the fluctuation has been very much more in the price of silver than in the price of gold; a difference of 1*d.* an ounce in each being equal to a variation of 15 to 1 against the standard price of silver as compared with gold.

But it is not sufficient to consider the demand for the precious metals as articles of consumption only; they are suddenly sought for in large quantities for other purposes. If the exchanges be unfavourable to a country, its precious metals are in greater demand for exportation than its commodities; or if there be a foreign war, its metals are in demand for the payment of the troops and for the purchase of food and munitions of war, simply because of their ready convertibility. This applies with peculiar force to gold. It is because of its superiority as a medium of exchange and standard of value that it is taken.

If it should happen that one country has a large gold coinage in circulation in addition to all the bullion which is required for the purposes of commerce, while all the adjacent countries use a silver currency, and possess very little more gold than is necessary for its consumption, it is clear that whenever a large demand for gold arises, it must be directed to the country in which there is a gold currency. The gold in the other countries has, in fact, become higher in value from the increased demand, and so soon as the increased value makes it worth while, the gold in the country where it has not yet risen, will be immediately used by all others as a rich gold mine, whence abundance of metal without alloy, and assayed ready to their hands, may at once be grasped, without digging in the earth. No laws and no vigilance can restrain its export: as soon as it is wanted abroad, it disappears like water through a sieve. Whenever gold is wanted, the coinage of England, if there is not a sufficient supply of bullion, supplies it to those countries having a silver standard; while if England requires silver it is rapidly drained from those countries. The extent to which gold is exported when the foreign exchanges are unfavourable may be seen from the returns of bullion retained by the Bank at many different periods. We have already stated the large amount of silver obtained from France in 1859.

But it must be recollected that, independently of fluctuations in the prices of bullion, a diminution in the quantity of money circulating in a country raises the value of the remainder, and disturbs its relation to the prices of other commodities. It is in this form that the effects of an abstraction of gold must be felt rather than in the price of bullion; and though its influence upon prices is very injurious, the cause is not always perceptible. When paper money is added to gold and silver coin as part of the circulation, a country can always command a sufficient quantity of money; but the drain of its metals has an important influence upon the value of its circulating medium, and upon the operations of commerce.

But the precious metals, even gold, have an inconvenience from their bulk, the dangers of transit in large quantities, and the need of at least occasional assaying. In all commercial nations the use of paper money is almost imperative, and its convenience makes it in various respects desirable even in the internal trade of a country. Its value however as a medium of exchange is merely that it is a guaranteed representative of real value. This guarantee may be afforded by the issue of paper either immediately by a government, or by its delegated agents; and no paper can be kept up to its nominal value unless it is known to be readily convertible into real value at any time at the desire of the holder. The paper money of most of the continental states is at a considerable discount from not being so convertible, and the state itself does not receive it in payment of taxes or duties, for instance, at the full amount it nominally represents. Further information on this

subject will be found in the articles BANK and BANKING; BILLS OF EXCHANGE; EXCHANGE; CURRENCY, &c.

Money, as a circulating medium, is either of metal coined for the purposes of commerce, usually stamped with the name and arms of the prince or state that directs it to pass current; or it is money of account, which may be considered with respect to coins as weights and measures with respect to goods, or as a mathematical scale with respect to maps, lines, or other geometrical figures. Thus moneys of account serve as standards of the value both of merchandise and of the precious metals themselves. It should, however, be remarked, that moneys of account, though they are uniform as a scale of divisions and proportions, yet they fluctuate in their intrinsic value with the fluctuation of the coins which they measure or represent.

The earliest currency of metal has been already treated of under COIN, together with the denominations, as far as they are known, of the different moneys current among the chief nations of antiquity, as well as some in our own country.

Several other of the more important coins, ancient and modern, have been already disposed of under their respective heads; we shall now lay before our readers as concise an account as possible of the money which forms the present, or has formed the recently existing, metallic currency of modern nations, taking them alphabetically:—

Albert's Dollar is a coin formerly known in Holland, with its half and quarter, at 50, 25, and 12½ stivers. The term is used also as a money of account at Libau and Riga. The intrinsic value of a metallic Albert's dollar was 4s. 4½d.

Altmichlic, a Turkish silver coin, no longer in use.

Ana, an East Indian coin, the 16th part of a rupee; worth about three halfpence.

Asper, a small Turkish money of account.—3 aspers = 1 para; 40 paras = 1 piastre.

August d'Or, a gold coin of Saxony, double, single, and half; reckoned at 10, 5, and 2½ rix-dollars. The august piece of 5 thalers was worth 16s. 5½d. It is now disused.

Bajoccho, or *Soldo*, a copper coin at Rome, formerly divided into 12 denarii, or 5 quattrini; worth about the third of a penny. There are also double and single bajocchelli, of 4 and 2 bajocchi. 100 bajocchi = 1 scudo romano.

Batzen, a base silver coin formerly used in Switzerland, and also in some parts of Germany. It was worth about 1½d. English.

Beshlik, a Turkish and Egyptian coin: worth, in Egypt, about 2s. 3½d.; in Turkey, 1s. 0½d. The beshlik in Syria is a mixed metal, and is worth about 10d.

Bit, or *Bitt*, a small coin in the West Indies, worth 5½d.

Candereen, a part of the currency of China, passing by weight; 1000 candereens = 1 tael, which is worth 6s. 7d.

Carlino, a small silver coin in the kingdom of Naples and in Sicily: it contains 10 grani, worth 4d. There are mezza-carlini, of half the value. In Piedmont the carlino was a gold coin: coined before 1785 it was of the assayed value of 5l. 18s. 8d.; subsequent to that year, 5l. 12s. 3d.; the half, &c., in proportion.

Carolus d'Or, or simply *Carolus*, a gold coin of Bavaria, Hesse-Darmstadt, and Würtemberg, now disused, value 20s. 6d.

Cash, a small coin in China, and India beyond the Ganges. It is the only coin used in China. It is not coined, but cast. It is composed of 6 parts of copper and 4 of lead; round, marked on one side, and rather raised at the edges, with a square hole in the middle. These pieces are commonly carried like beads on a string or wire. A tael in account of fine silver should be worth 1000 cash, or about 6s. 7d.; but, on account of their convenience for common use, their price is sometimes so much raised that only 750 cash are given for the tael. Cash is sometimes called *Caza*. In Sumatra cash are small pieces of tin or lead, 2500 of which go to a mace.

Cent, or *Centime*, a coin and money of account in France, Holland, Belgium, Switzerland, and in the United States of North America. In France the centime is the fifth part of a sous (about an English half-penny), and hundredth part of the franc (worth 10d. English). In Holland 100 cents = 1 florin. In Switzerland the small coins consist of pieces of 5, 10, and 20 centimes, in base metal, less bulky than the English copper. Centimes are sometimes called *rappen*, which were formerly the tenth part of a batzen. In the money of the United States the cent is the hundredth part of a dollar. Half-cents are coined in the same proportion.

Christian d'Or, a former Danish coin, worth 16s. 5½d.

Copang, or *Coban*, a Japanese coin. The old copangs weigh 371 Dutch asen, or 275 English grains, and the gold is said to be 22 carats fine: this would give 2l. 4s. 7d. sterling for the value of the old copang; but it must be observed that the Japanese coins are reckoned at Madras only 87 touch, which is 20²³/₁₀₀ carats, and this reduces the value of the old copang to 2l. 1s. 10d. sterling. The new copangs weigh 180 English grains, and the gold is about 16 carats fine, which gives their value 21s. 3d. sterling.

Copeck, see *Kopek*.

Cowries, a species of small sea-shells, which, as long as they remain unbroken, are used in parts of Africa, India, &c., as money in small payments: 2560 cowries are generally reckoned for a current rupee. But they have intermediate divisions, thus: 4 cowries make 1 gunda; 20 gundas, 1 punn; 4 punns, 1 ana; 4 anas, 1 cahaun; and 4 cahauns

1 current rupee; but the last proportion is variable. Cowries are also used for money on the Malabar coast, at Siam on the farther peninsula, and in Guinea, where 2000 of these shells are called a macuta.

Crore, a money of account in the East Indies, equal to 100 lacs, or ten millions of rupees.

Crown.—In England, Henry VII. was the first king who coined a crown in gold. He afterwards, as has been already noticed, struck some patterns for a crown in silver; but Edward VI. was the first who coined the silver crown and half-crown for currency. From Elizabeth to Victoria the silver crown and half-crown have been struck in every reign. It is now current for 5s., weighs 18 dwts. 4¹¹/₁₆ grs. The half-crown is of half the weight and value. The croone, or crown, was formerly a coin of the Netherlands; those after 1755 were estimated at 2 florins 14 stivers of exchange, or 3 florins 3 stivers current. It was also a coin of Denmark; double, single, and half-crowns were reckoned at 8, 4, and 2 marks crown money, or 8 marks 8 skillings, 4 marks 4 skillings, and 2 marks 2 skillings current.

Crusado, a silver coin in Portugal, of 480 rees, or 2s. 2d.

Decime, a money of account, and coin in the Revolutionary system, of France: 10 decimes make the franc, or 100 centimes. There were copper pieces of 1 and 2 decimes.

Denier was the 240th part of the livre, or French pound.

Dime, a money of account and silver coin in America, is the 10th part of a dollar. There are also half-dimes.

Doblon, or *Doublon*, a Spanish gold coin, the ancient value of which has been changed up to 1772, when the former pieces were called in; the doubloon was of the value of 3l. 1s. 10d. The present *doblon* is worth 3l. 4s. 8d. The double and the half of each in proportion.

Doppia, or *Pistole*, an old Italian gold coin, of which the value varies in different states. The Roman *doppia* was 15³/₄ lire, or 13s. 8½d.; that of Parma was 26 lire 14 soldi. The *doppia* of Genoa was worth about 31s. 3d., but few are in circulation, as the Sardinian coinage is now assimilated to that of France.

Doit, or *Duyt*, a small Dutch copper coin, now disused, the 8th part of a stiver, in value half a farthing.

Dollar.—The dollar of the United States of North America, weighing 416 grains of standard silver, is valued at 4s. 4d. English. It has on the edge, "ONE DOLLAR OR UNIT HUNDRED CENTS," and has its divisions of half and quarter. By an Act of 1837, the silver dollar of the United States is required to contain 412½ grains of standard silver, of which one tenth is alloy, which is now the proportion in all coins of the United States, whether of silver or gold. The Spanish dollar of the old sort, before a new coinage took place in 1772, was of the sterling value of 4s. 4½d. Till then there were dollars of two denominations, the Mexican and the Sevillian dollar. That which is at present generally circulated as the Spanish dollar is really of the sterling value of 4s. 3½d. The Greek silver dollar is worth 3s. 6½d., and the five-dollar piece is a gold coin of the value of 17s. 8½d.

Drachma, a silver coin of the kingdom of Greece, worth about 8½d.

Ducado, is an imaginary Spanish money, often used in estimating or stating values; it is reckoned at something more than 2s.

Ducat, *Danish*, a gold coin worth 7s. 5½d.; the specie ducat is worth 9s. 4d.

Ducat, *Dutch*, a gold coin, now called in, of the value of 5 guilders 2 stivers. English value, 9s. 4½d.

Ducat, *German*, also a gold coin, the rate of coinage of which, although each state has its own ducats, is nearly the same all over Germany, in Hungary and Bohemia; that is, about 9s. 4½d. or 9s. 5d. The ducat of Holland is 9s. 4d. The Austrian double ducat is in proportion. The ducat of Baden, however, of five gulden, coined from 1819 to 1827, is only worth 8s. 5¹/₂. The ducat of Saxony is current at 9s. 5d.

Ducat, *the Italian*, is a silver coin and money of account at Naples and other places. The Neapolitan ducat is worth 3s. 4d. The Venetian silver ducats of a former time varied both in weight and fineness. In weight from 13 dwt. 18 gr. to 14 dwt. 19 gr.

Duro, a gold coin of Spain, worth about 4s.; with its double, the *dos duro*. The old Spanish silver dollar is also known as the *duro*.

Eagle, an American gold coin, of the value of 10 dollars, or units. Its intrinsic value in English gold was nearly 2l. 3s. 9d. Since 1834 it has been reduced in value. It now contains 258 grs. The value is now 41s.

Ecu, a silver coin in the old system of France, and also at Geneva and other places in Switzerland. In France it was of 6 livres; and the *Petit Ecu*, or half-crown, of 3 livres. The *ecu*, or *patagon*, of Geneva was worth 3 livres or 10½ florins. Those coined in 1796 were of the English value of 4s. 9d.

Escalin.—The escalin, or shilling, was formerly a base silver coin in the Netherlands, at 6 stivers of exchange, or 7 stivers current. Of the English value of 6d., and its double in proportion.

Fanam, a small coin in the East Indies, both of gold and silver, now disused. The gold ones were alloyed with silver, and 24 of them were reckoned for an old Negapatam pagoda, which went for 8s. The silver *fanam* of Bombay was worth about 4½d.; that of Pondicherry 3½d.

Farthing, an English copper coin, the fourth of a penny. It is said to have been a round coin in the time of some of the later Saxon kings; they usually at that period consisted of the fractions or parts

of the penny broken into four. Instances of pennies neatly and accurately cut into halves and quarters occur almost wherever Saxon coins have been discovered. The fourthling, as money, is twice mentioned in the Anglo-Saxon version of the Gospels. (Matt. v. 26; Luke xxi. 2.) Half-farthings were coined in 1852, chiefly for the use of the British colonies.

Faruki, a gold coin of Mysore, struck by Tippoo Saib, of the value sterling of 7s. 11d. A variety of the pagoda.

Filippo, or *Philip*, an old silver coin of Milan, worth about 4s. 8½d.

Florin, a money of account and silver coin in Holland, Belgium, and Germany, called also gulden and gülden, and, by corruption, gilder or guilder. The florin of Holland and Bavaria is worth about 1s. 8d.; that of Belgium is equal to a franc, or 100 centimes; the heavy (or *conventions münz*) florin of Austria is worth about 2s. 4d., but coin is rare throughout the Austrian dominions; paper supplying its place down to notes of 6 kreutzers. At Frankfort-am-Maine it is only worth 1s. 7d.

Florin is also a gold coin at Hanover and in other parts of Germany, though chiefly current in the countries on the banks of the Rhine; passing generally for 2 rix-dollars current. Assay value about 6s. 11d.

Florin is also the name of an English silver coin current for 2s., and weighing 7 dwts. 6½ grs. It was also the name of an earlier English coin, both in gold and silver. [COIN.]

Fourpenny-piece, an English silver coin, the third part of a shilling, weighing 1 dwt. 5½ grs. There are also silver coins for *threepence*, *twopence*, and *pence*, but the last-named two are not coined for general circulation, and are only given in small numbers as Maunday money.

Franc, a money of account and silver coin of France, Sardinia, Switzerland, and Belgium, with its double, quintuple, and lower proportions, down to 1-5th of the French franc, weighs 77.17 grains, contains 69.453 grains of pure silver, and is worth 10d. Those of Belgium, Sardinia, and Switzerland are very nearly the same. The gold coins are pieces of 40, 20, and 10 francs, value 31s. 9d., 15s. 10½d., and 7s. 10½d. The old Switzerland franc was worth 1s. 2d.

Frederick, or *Friedrich's d'Or*, a gold coin in Prussia and Denmark, worth 16s. 5½d. There are also double and half Fredericks.

Ghuzih, a Turkish silver coin, equal to 25 piasters, or about 4s. 6d. In Syria, it is a gold coin, but the value is somewhat less.

Gilder, or *Guilder*, see *Florin*.

Giulio, a small coin of base silver, formerly current in Italy; half a lira.

Gold Crown, a coin of Portugal, worth 1l. 3s. 11d.

Grano, a copper coin, and the money of account in Naples, Sicily, and Malta. It is worth 4-10ths of an English penny.

Groschen, a small coin, and money of account in Prussia, Hanover, and other parts of Germany. A Prussian silver groschen is worth a penny English. There are also coins of 10, 5, and 2½ groschen. The *gute groschen* of Hanover are 24 to the thaler, and worth nearly 1½d.

Grosso, a silver coin of central Italy, worth about 2½d.

Grote, a small coin and money of account, in use at Bremen: 74 grotes make 1 rix-dollar. It is worth rather more than a halfpenny.

Guilder, see *Florin*.

Guinea.—The unit, as it was called, or twenty-shilling gold piece, was first coined by King James I. The appellation of *Guinea* was given because great quantities of them were coined out of gold brought from the Guinea coast by the Royal African Company, which are distinguished by an elephant under the head, some a castle, others without. The guinea had not been long in currency before common consent had raised it to 21s. About the æra of the Revolution, James II.'s guinea was paid and received at 21s. 6d. In the reign immediately subsequent, the gold money remaining without alteration in weight and fineness, and the silver money growing daily of less value by clipping and counterfeiting, occasioned 25s., then 28s., and at last 30s. to be given for a guinea; but no sooner was the silver money restored to its first value by the grand recoinage, than the guinea was again reduced, first to 28s., then to 26s., and finally to 22s., and soon after, by common consent, was paid and remained as before at 21s. 6d., and continued at that price for twenty years after. In 1717 the guinea was reduced to 21s., at which it continued till the latter part of the reign of George III., when the coining of guineas ceased.

Gulden, a silver coin of Holland, equal to 20 stivers; in Bavaria, 1 gulden = 60 kruzen; they are both worth 1s. 8d. English.

Heiler, is a copper coin, formerly used through most parts of Germany, and worth about a halfpenny English.

Imperial, a Russian gold coin, of 10 rubles; it has its half. The English mint value of the imperial is 34s. 4d., and of the half 17s. 2d.

Joanese, *Johanes*, or *Joe*, a former Portuguese gold coin (called also a *Portuguese*), of the value of 1l. 11s. 10d.

Isabelino, a gold coin of Spain, worth 1l. 0s. 10d.

Khereeh, a gold coin of Egypt and Turkey. That of Egypt is worth about 4s. 7d.; that of Constantinople, about 4s. There are, however, several khereehs, varying in value.

Kopek, or *Copeck*, a money of account and silver and copper coin in Russia. In silver there are pieces of 30 kopeks down to 5: the copper kopek, also in pieces of 10, 5, 3, 2, and 1, is worth about three-fourths of a halfpenny. It is the silver kopek that is the money of account: 100 kopeks = 1 ruble.

Kreuzer, a small copper coin, and money of account in many parts

of Germany, worth ½ of a penny. Sixty kreuzen go to a silver gulden of Holland or Bavaria.

Lac, a money of account in the East Indies; it is equal to 100,000 rupees.

Larin, an old coin and money of account in Persia and Arabia, of 2½ mamoodis. It consists of a silver wire, about half an inch in length, doubled up, and flattened on one side to receive the impressions of some characters.

Lepton, a copper coin of the kingdom of Greece, the 100th part of a drachma. The piece of 5 lepta, the smallest coin in use, is nearly equal to a halfpenny.

Liard, a small French copper coin in the old system of France, of the value of 3 deniers.

Lira, a gold coin of Turkey, circulating chiefly in Syria and Palestine, of the value of about 18s. 6d.

Lira, a silver coin of Italy, particularly at Milan and Venice. It is in fact the Austrian zwanziger. The lira of Lombardy is current for about 8½d. The *nova lira* of Sardinia was equivalent to the French franc. The currency of Lombardy and Tuscany is in a state of transition, being assimilated to that of Sardinia.

Lirazza, base silver pieces, formerly current at Venice, of 30, 20, 10, and 5 soldi.

Livornina, an old silver coin of Leghorn, value 4s. 5½d.

Louis blanc, the name for the old ecus of silver coined in France before 1726, at the rate of 9 pieces to the mark of 10 deniers 22 grains fine.

Louis d'or, a former gold coin of France, at first worth 20s. 1d., but reduced in 1786 to 18s. 10d.; it is now valued at 19s.

Lowen Dollar, or *Lyon Dollar*, an old Dutch silver coin at 42 stivers or a little more. It was ¾ of the ducat.

Mace, a small gold coin in Sumatra, weighing 9 grains, and worth about 14d. sterling. In China the mace is the tenth part of a tael.

Mamoodi, or *Mamoudi*, a money of account and silver coin of Persia. The mamoodi of Gombroon contains ¾ silver and ¼ copper, and is worth nearly 3d. The mamoodi of Bassora is worth about 5½d.

Maravedi, is now a Spanish money of account, but was formerly a coin. It is now reckoned as the 34th part of a real.

Mark, an old English gold coin, worth 13s. 4d.

Mark, a silver coin in Denmark, Norway, and Hamburg. The Danish mark is equal to 16 skillings, and is worth 4½d. The mark of Hamburg is equal to 16 schillings, and is worth about 1s. 3d.

Max d'Or, or *Maximilian*, an old gold coin of Bavaria, value 13s. 8d.

Mejideh, a Turkish silver coin, circulated in Syria, worth about 3s. 6d.

Milreis, a coin of Portugal = 1000 reis, and worth 4s. 6d. The milreis of Brazil is reckoned at 3s. 7d. only.

Moeda, a Brazilian gold coin, worth 1l. 15s. 7d.

Mohur, a coin of gold in the East Indies. The mohur or gold rupee of the emperor Shah Allum, 1770, was of the value of 1l. 13s. 0½d.; the mohur of the same, 1787, 1l. 13s. 4½d.; the sicca gold mohur of Bengal, of 1789, 1l. 13s. 7d.; the old Bombay mohur, 1l. 10s. 1d.; Surat mohur of the latest coinage, 1l. 9s. 2½d.; Tippoo's gold rupee, 1l. 12s. 1½d.; mohur of the Dutch East India Company, 1783, 1l. 12s. 1½d.; ditto, 1797, 1l. 10s. 10½d. Some of these had halves and quarters in proportion. The present mohur is worth 1l. 9s. 3½d.

Moidore, a former gold coin of Portugal, of 4800 reis, of the value of 1l. 1s. 8d. sterling.

Napoleon, a gold coin of France, the successor of the louis-d'or, of the value of 20 francs. The value is 15s. 10d.; of the half-napoleon or 10-franc piece, 7s. 11d.; of the double, or 40-franc piece, 1l. 11s. 8d. The napoleon weighs 99.564 grains, and contains 89.61 grains of pure gold.

Noble, an old English coin, worth 6s. 8d.

Oban, the largest gold coin of Japan, three times the value of the copang.

Oboli, and *obolici*, moneys of account in the Ionian Islands; 104 oboli = 1 dollar, worth 4s. 4d.; 5 obolici = 1 oboli, which is worth an English halfpenny.

O'havo, the smallest copper coin of Spain; it is reckoned equal to 2 maravedis, or the 17th part of a real.

Onza, a Sicilian gold coin of the value of 30 tari, each taro being subdivided into 20 grani. Its value is about 10s. 3½d. There is another onza, of a later coinage, of exactly double the weight and value.

Onze de oro, a Spanish gold coin; the same as the doblon.

Ora (from the Saxon *ore*, metal), a money of account among the Anglo-Saxons, whatever it might have been in other parts of Europe. In the Domesday Survey, it is used for the ounce, or a twelfth part of the nummular pound. There appear to have been two sorts of ora in use in the Saxon times, one of sixteen pence to the ora, the other of twenty pence. The ora of Domesday Book is perpetually valued at twenty pence. The ora of sixteen pence was of earlier date.

Ort, a coin of Norway, called in some parts a mark, and worth about 10½d.

Pagoda, a gold coin on the Coromandel coast, in the East Indies, now disused, of which there were several kinds: namely, the star

pagoda of the value of 7s. 5½d.; old Arcot pagoda, 7s. 2d.; new Arcot pagoda, 5s. 8½d.; Onore pagoda, 7s. 10d.; Mangalore pagoda, 7s. 10½d.; pagoda with a crescent and one figure, 7s. 6d.; pagoda of Pondicherry, 6s. 5d.; Hyderee hoon, or pagoda, 7s. 8d.; Sultannee hoon, or pagoda, 8s. 5d.; Tippoo's farufei, 7s. 11½d.

Paolo, a small silver coin at Florence, Rome, and other place in Italy, with its double, half, and quarter. The value of the paulo is 5½d.

Papetto, a small silver coin of Rome, value 10½d.

Palaca, a Brazilian silver coin, worth 4s. 2½d. It is often called the Brazilian dollar.

Para, a Turkish and Egyptian money of account. The five para piece is the only copper coin in Egypt. 40 paras = 1 piastre.

Penny.—The early English coins of this name were of silver, and of varying worth. It has been long the largest current copper coin, the twelfth part of a shilling; the fractional halfpenny and farthing are also common; but there has been no copper coin of larger value since the twopenny-piece of George III.

Peseta, a Spanish silver coin, now disused; the old Mexican peseta of two Mexican reals, 1736, was of the value in sterling of 1s. 1d.; the peseta is now about equal to the French franc, or 9½d.

Peso, an imaginary Spanish money frequently used in expressing values, and reckoned at about 2s. 8d. The peso is used in regulating the exchange with foreign countries.

Peso duro, a money of account at Gibraltar, worth 4s. 2d.

Pezza, a gold coin of Sicily, now seldom seen, of which the value was 21s. 3d. It is now a Maltese silver coin, worth 4s. 2d.

Pfennig, a Hamburg coin, of which 12 = one schilling, and 16 schillings = 1 mark, which in the currency (which varies from banco, the money of account) is worth 1s. 2½d.; the mark banco is reckoned at 17½d. In Hanover 24 pfennigen = 1 gute groschen. In Prussia the pfennig is worth one-tenth of an English penny.

Piastra, a silver coin of Naples, now disused, worth 4s. English. There was also a mezza-piastra, of half the value.

Piastre, a money of account and a silver coin in Turkey and Egypt. The piastre of Mustapha III., 1757, was of the sterling value of 1s. 10½d. The piastre of Egypt, of 40 paras, is now worth only 2½d., and that of Turkey, 2½d.

Pice, a money of account and a copper coin in the East Indies; 14 pice are equal to one ana, a pice is therefore worth half a farthing.

Piece of Eight, the old Spanish dollar; also a money of account in what used to be the Danish West India Islands.

Pistole, German, is the common name of coins bearing the name of the state in which they circulate, or the sovereign who coined them. They vary slightly, and an allowance is made for deficiency in weight and fineness; 35½ pistoles should weigh a Cologne mark of gold, 21½ carats fine; they are then called *passir pistoles*, and are worth from 16s. 4d. to 16s. 6d.

Plates, the denomination given to certain large copper coins, formerly used in Sweden. Kelly says, "The large copper pieces of the value of 4, 3, 2, 1, ½, and ¼ silver daler, or 12, 9, 6, 3, 2½, and 1½ copper daler, weighing 7½, 5½, 3½, 2½, 1½, 1½, and ¾ lb. of the victualie or common weight, are no longer considered as a legal coin, but as a sort of merchandise, which every one is at liberty to sell or export after paying the duty on exportation. These in general, but more particularly the 2-daler pieces, are called plates."

Plott, a silver coin formerly used in Sweden, ½ of the rix-dollar, of the value of 1s. 6d. sterling.

Pol, a Russian gold coin; it is the name of the half-imperial, and is worth 17s. 2d.

Poltn, *Poltina*, *Popoltin*, Russian silver coins, of 50 and 25 kopeks, = to the half and quarter ruble. The poltn of the empress Anne was of the value of 1s. 9d.; that of Elizabeth, 1s. 10d.; of Catherine II., 1s. 7½d.; of Paul, 1s. 7½d.; of Alexander, 1s. 7d. The halves in proportion. None of these are now used.

Polturat, a coin of Hungary, not now in use. The currency in all the Austrian possessions is now assimilated.

Quarter, a money of account and coin in Bombay, of which 4 make a rupee.

Quarto, a money of account at Gibraltar; 16 quartos are equal to 1 real, 12 reals are equal to 1 peso duro or dollar. The quarto is therefore rather more than the third of a penny.

Quattrino, a copper coin in Italy, of 2 denarii, now disused. At Rome 5 quattrini made 1 paulo.

Real. There were formerly three small Spanish silver coins called reals, namely, the real of Mexican plate, the real of provincial plate, and the real vellon. The real now is a silver coin, worth about 2½d.; there is also a double real. Twenty reals = 1 duro.

Reas, a money of account in Bombay, of which 400 go to a rupee.

Ree, a Portuguese and Brazilian money of account. The five-ree piece, a copper coin, is worth a little more than a farthing. The milris (or piece of 1000 reis) is worth 4s. 6d.

Rigsbank Daler, a money of account in Denmark, worth 2s. 2d. The specie daler is worth double that sum. 96 skillings = 1 rigsbank daler. In Sweden the rigsbank daler is only worth 1s. 8d., but the specie daler is worth 4s. 4d.

Riedollar, a silver money of Hamburg and Lubeck, equal to 3 marks. It is also a coin of Bremen, worth 3s. 4d. It is also used at the Cape of Good Hope, where (in paper) it passes for 1s. 6d.

ARTS AND SCI. DIV. VOL. V.

Ruble, or *Rouble*, a money of account, and a silver coin in Russia; it is equal to 100 copper kopeks, and is worth 3s. 1½d. English. There are pieces of ¾ and ½ a ruble also.

Rundstyken, a money of account and coin in Sweden, worth the 12th part of a halfpenny; 12 rundstyken = 1 skilling.

Rupee, a money of account and silver coin in the East Indies. The coins, which were formerly struck at the Calcutta mint, were sicca rupees, also called silver rupees, and gold mohurs, sometimes called gold rupees; 16 of the former, by regulation, were to pass for one of the latter. The silver rupee has its half. The present rupee, called the Company's rupee, contains 16 anas, and is reckoned at 2s. sterling.

Schilling, a coin of Hamburg, of which 16 = 1 mark; it is therefore the 16th part of 1s. 2½d. In Mecklenburg Schwerin it is the 24th part of a neue thaler, which is worth 2s. 3d.

Schwaren, a coin of Bremen; 5 schwaren = 1 grote; 72 grotes = 1 rix-dollar; the schwaren is therefore worth the 9th part of a penny.

Scudo, a money of account, and a silver coin in many parts of Italy, at Sicily, and Malta. The scudo of Rome is worth 4s. 2½d.; that of Tuscany about 4s. 5d.; that of Sicily and Malta about 4s. 1d. The ten-scudo piece is a gold coin.

Sequin, or *Zecchin*, Italian, called also *Gigliato*, a former gold coin of Venice, Genoa, Rome, Milan, Piedmont, and Tuscany, of the average value of 9s. 4½d. It is also used in Algeria, where it is worth 6s. 10½d.

Sequin, or *Checqueen*, Turkish; the gold coins of Turkey are the sequin funduculi, with halves and quarters; the double sequin, or yermeebeshlik, and the roubieh. There are other sequins beside the above, which bear different names, and their values also vary according to the periods of their coinage. The sequin of Egypt is valued at 5s. 4½d.

Shilling, an English silver coin, the twentieth part of a pound, and weighing 3 dwts. 15½ grs. It represents the old Saxon scilling; it was also called a testoon, from the head on it when coined by Henry VII.

Shoe of gold, an ingot, used as money in China. The name is English. Kelly, speaking of China, says, "Gold is not considered as money, but as merchandise; it is sold in regular ingots of a determined weight, which the English call *shoes* of gold; the largest of these weigh 10 taels each, and the gold is reckoned 94 touch, though it may be only 92 or 93."

Sixpence, an English silver coin, the half of a shilling, weighing 1 dwt. 19½ grs.

Skilling, a copper coin of Denmark, worth about a farthing. The Norway skilling is worth nearly a halfpenny.

Soldo, a small copper coin of Italy. There are half soldi, and quattrini, the fifth part of a soldo.

Sou, or *Sol*, a money of account and copper coin in France and Switzerland. It is equal to 5 centimes, and is worth about a halfpenny.

Souverain, a former gold coin of Austria. Its value was 13s. 11½d. There were also half and double souverains.

Sovereign, the name of an English gold coin in use as early as 1526; but name and coin were discontinued till revived in the latter end of the reign of George III. and applied to the coin now forming the unit of our gold currency. The sovereign weighs 5 dwts. 3¼ grs., and is worth 20s. of the Mint standard gold of 22 carats fine. The half-sovereign and double-sovereign have precisely proportionate values.

Stiver, a money of account and copper coin in Holland and the Netherlands, containing 2 greets Flemish, or 8 duyts, or doits, and valued at one penny English. It is also used as a money of account in Denmark: 96 stivers = 1 rigsbank daler.

Tael, a money of account in China, reckoned at 6s. 7d.

Taro, a silver coin of Sicily and Malta, of the value of 4d.

Testone, or *Testoon*, a silver coin in Italy, and also in Portugal. In Italy the testone of Bologna is rated at 30 soldi; at Parma the testone is of 6 lire 6 soldi; at Rome of 6 paoli. Kelly gives the sterling value at a little more than 1s. 3d. The value of the Portugal testoon is 5½d.

Thaler, is the German dollar, of which almost every state has its own. The specie dollar varies but little in value, which is about 4s. 0½d. The current thaler and the reichsthaler are moneys of account, worth about one-third less. The Prussian, Hanoverian, and Brunswick thaler is worth 2s. 11d.; the Convention thaler about 3s. 11d.; the Kron thaler about 4s. 6d.: all circulate in the north of Germany.

Tornese, a copper coin of Naples, of the value of half a grano, or ⅓ths of an English penny.

Vintem, a Portuguese and Brazilian copper coin, worth 20 rees; there are also 3, 6, and 12 vintem coins in silver.

Zwanziger, or *Kopfstück*, of Würtemberg, is a silver coin worth 8d. English; the name is properly Austrian, where it passes for 20 kreutzers, while in Würtemberg and Bavaria it passes for 24.

There are, no doubt, numerous others both as coins and as moneys of account, but the most of them will be found local, and comparatively unimportant. The progress in every civilised country has been to simplify its currency; and in various instances to assimilate it to that of a neighbouring country, or of one with which they have much commercial intercourse. For further information see *The Modern Cambist* by W. Tate. In most of the continental countries of Europe, except France, Holland, and Belgium, the greater part of the currency consists of paper.

MONK. [MONACHISM.]

MONOCEROS (the Unicorn), a constellation of Hevelius, surrounded

by Hydra, Canis Major, Orion, and Canis Minor. It does not contain any stars of conspicuous brightness.

MONOCHORD (*μόνος*, *one*, and *χορδή*, *a string*), an instrument of one string, used for the purpose of ascertaining and demonstrating the relative proportions of musical sounds. It is composed of a board, or rule, divided and subdivided into various parts, and of a string distended between two bridges, one of which is placed at each end of the rule. There should also be a moveable bridge applicable to the graduated line, in order to stop the string at the distances required, leaving both hands of the operator at liberty; but this is not indispensable. The invention of the Monochord is attributed to Pythagoras, and Ptolemy measured and proved all his intervals by it. Guido also, in his 'Micrologus,' strongly recommends the use of this instrument, and gives ample directions for its division, according to his system, for a translation of which we refer the reader to Hawkins's 'History,' i. 449. In Dr. Crotch's 'Elements of Musical Composition,' will be found a simple and cheap method of constructing a Monochord, with plain rules for dividing it for common practical purposes.

MONOGRAM, a cipher or character formed by an interlacing of letters, intended as an abbreviation of a name. Monograms are of very ancient date. They are not uncommon upon Greek coins, especially those of Macedonia and Sicily. They likewise occur upon the coins of the Seleucidae, and are found upon many of the family coins of Rome, though not upon those of the Roman emperors till a late period.

The monogram of Jesus Christ  upon the coins of Constantine the Great, is well known. It was continued frequently by his successors, even as low down as Alexander Comnenus and Theodorus Lascaris, and was also placed at one period upon the Roman labarum.

Montfaucon, in his 'Palæographia Græca,' p. 144, has given a small plate of monograms used on coins, and, in ancient manuscripts, to represent the names of Greek cities. Such will also be found in Schlæger, 'Comment. de Numo Alex. M.,' tab. 3; and in Frölich, 'Annal. Reg. Syr.,' tab. 20. Dr. Charles Combe, in the 'Museum Hunterianum,' 4to, Lond., 1782, plates 63 and 64, has given no less than four hundred and twenty monograms which occur upon the coins of Greek states and cities: others will be found in tabb. xiv., xv. of the 'Veterum Populorum et Regum Numi qui in Museo Britannico asservantur,' 4to., London, 1814: and see the works on numismatics generally.

The conjunction of two, three, or four letters together is not uncommon in Greek and Roman inscriptions. Many of those of the Roman time will be found in Gerrard's 'Sigillarium Romanum,' 4to., Lond., 1792. Père Menestrier has preserved those of many of the popes. Ducange, in his 'Glossary,' has given tables of those of the popes, emperors, and the kings of France. Monograms appear upon almost all the coins of the kings of France of the second race, that is, from A.D. 751 to 987. (Le Blanc, 'Traité Historique des Monnoyes de France,' pp. 87-144.) Eginhard gives as a reason for Charlemagne's using a monogram upon his coins, that he could not write; and Le Blanc adds that a great many bishops did the same for the same reason, which is absurd, as at that period it was the fashion of Europe generally. They appear upon our own Saxon coins, and especially upon those of Alfred.

Monograms were almost universally used by the early engravers. Bartsch, in his 'Peintre Graveur,' has given tables of the monograms used by those of Germany and Italy. The French artists more rarely used monograms. Passavant, in his 'Peinture Graveur,' gives the monograms omitted by Bartsch. Bryant, in his 'Dictionary of Painters and Engravers,' has several plates of monograms; and indeed, most recent writers on engraving have supplied their readers with the monograms of the engravers whose works they notice. The most extensive information however on this class of monograms will be found in the best edition of Brulliot's 'Dictionnaire des Monogrammes, Marqués figurées, Lettres initiales, Noms abrégés, &c. avec lesquels les Peintres, Dessinateurs, Graveurs, et Sculpteurs ont désigné leurs Noms,' 2 tom. 4to., Munich, 1832. M. Alphonse Wyatt has in a series of papers (with fac-similes) in vols. i. and ii. of the 'Gazette des Beaux-Arts' (Par., 1859), opened up a previously untouched branch of the subject—the monograms affixed by celebrated amateurs to drawings and engravings which have formed part of their collections, and in the course of his investigations he has collected a great deal of curious information.

MONOMANIA. [INSANITY.]

MONOPOLY, from the Greek *monopolia* (*μονοπωλία*), which occurs in Aristotle's 'Politick' (i. 11), where it is used simply in the sense of a man buying up the whole of a commodity so as to be the sole holder of it, and to have the power of selling it at his own price. When the word *monopolium* was used by Tiberius in addressing the Roman senate (Suet., 'Tib.,' c. 71), he thought an apology necessary for introducing a new word. The word however soon came into common use. The term monopoly, which literally signifies *single* or *sole selling*, is used in a constitution of Zeno ('Cod.,' iv. 59) in the sense in which it is used by Aristotle, and in the sense of what our law understands by forestalling, engrossing, regrating, to which we may add combining to keep up prices. Zeno declares that no person shall exercise a monopoly of clothing, fish, or any other thing adapted for food or use. He gives no definition of monopoly. The term, however, must be explained from the context, from which it appears to signify any means by which a person gets or attempts to get the whole of any commodity into his

possession for the purpose of enhancing the price. In the same constitution he forbids all combination among dealers to raise the prices of any commodity. Zeno's punishment for monopoly was confiscation of the goods of the offender and perpetual exile.

A monopoly, according to the English law, is defined by Coke (3 'Inst.,' 181, c. 85, "against monopolists," &c.) to be "an institution or allowance by the king, by his grant, commission, or otherwise, to any person or persons, bodies politic or corporate, of or for the sole buying, selling, making, working, or using of any thing, whereby any person or persons, bodies politic or corporate, are sought to be restrained of any freedom or liberty that they had before, or hindered in their lawful trade." In 'Le Case de Monopolies' (11 Co., 86, b) it is said that every monopoly has three inseparable incidents—the raising of the price, the deterioration of the commodity, and the impoverishment of artificers and others. It appears that these inseparable incidents were considered as tests by which a grant savouring of monopoly might be tried.

Every royal grant or letters patent tending to a monopoly, as thus defined and explained, was void. The crown, however, could by letters patent grant and create exclusive privileges of buying and selling when such grant was of general use, or when the grant was to an individual who had introduced into the country something new and useful. This prerogative of the crown was often abused, and by none more than by Elizabeth, who granted many patents of monopolies for the purpose of raising money. As an instance of this, Elizabeth had granted to a certain person the sole making, importing, and selling of playing cards, which grant was declared void by the judges. ('Le Case de Monopolies.')

It seems, then, that the word monopoly was never used in English law, except when there was a royal grant authorising some one or more persons only to deal in or sell a certain commodity or article.

By the Act of 21 Jac. I., c. 3, all monopolies and all commissions, grants, licences, charters, and letters patent to any person or body politic or corporate, of or for the sole buying, selling, making, working, or using of any thing, or of any other monopolies, &c., are declared contrary to the laws of the realm and utterly void and of none effect.

By the sixth section of the same statute, the above provisions do not extend to letters patent and grants of privilege thereafter to be granted for fourteen years or under, of the sole working or making of any new manufacture to the true and first inventor thereof, which others at the time of making such letters patents and grants shall not use, so as also such letters patent be not contrary to the law or mischievous to the state, or generally inconvenient. This section is the foundation of the present law as to patents for inventions. [PATENTS.]

Copyright and patents are now generally placed among monopolies by legal writers, but not correctly. The original legal sense of the term monopoly has been already explained; and the power of the crown to grant patents is now limited and defined, as well as the several formalities to be observed in obtaining them. Any patent not obtained in due form is void; and the term monopoly, as above explained, has legally ceased to exist.

There is still a vulgar and common use of the term monopoly, which is incorrect, inasmuch as it has not the sense which monopoly had.

If a number of individuals were to unite for the purpose of producing any particular article of commodity, and if they should succeed in selling such article very extensively, and almost solely, such individuals in popular language would be said to have a monopoly. Now, as these individuals have no advantages given them by the law over other persons, it is clear they can only sell more of their commodity than other persons by producing the commodity cheaper and better. Such so-called monopoly, then, is neither the old legal monopoly, nor does it rest on any legal privilege. There would, however, be no objection to calling it a monopoly in the ancient sense of that term, if the word were not now used in a bad or unfavourable sense, which probably dates from the time when real monopolies were granted by the crown, and were very injurious to the nation. Between a monopoly as it once existed, and a monopoly as it is now vulgarly understood, there is this difference: the former was only derived from a grant of the crown, and was often injurious to all persons except the patentee; that which is now vulgarly called a monopoly is nothing more than the power which an individual or a set of individuals acquire, by means of capital and skill, of offering something to everybody cheaper and better than they had it before, and it is therefore an advantage both to the so-called monopolists and to everybody else.

The case of a number of persons combining to produce and sell, or to buy and sell, a thing, has been taken, as being one which is the most striking and oppressive kind of monopoly, in the vulgar sense of that term. An individual, however, may, in this sense, become a monopolist: as if a man should buy up all the tallow in Russia, and so make candles as dear as he pleased; or (to take a case which would appear a still greater act of monopoly, as being more sensibly felt), as if a man should buy all the corn in a country, and so make bread as dear as he pleased. Without discussing the question as to the advantages and disadvantages to a nation of this kind of monopoly, it is enough to put it upon those who disapprove of such wholesale buying, to say how far, and to what amount, they will allow a man to use his capital and exercise his commercial skill; for it is incumbent on those who would deprive a man of such liberty to say exactly how

far such liberty should go.* Further, if such persons wish to be exact in their language, they should use another word than monopoly, which had once a particular meaning, as above explained, and signified a different thing from that which they call a monopoly. And if they will apply this word monopoly to a person or persons who, by industry and skill, and the judicious employment of capital, make and sell, or buy and sell, much more of a thing than anybody else, they should consider whether—inasmuch as buying and selling are free to all, and as all people wish to buy as cheap as they can, and as good as they can—they will apply this word in an invidious sense to any person or persons who can only command customers because the customers like to go to them, or because the customers can get the thing nowhere else, owing to no other persons having provided themselves with the commodity for sale.

That kind of monopoly, or sole-selling, or dealing, which is given by the law of copyright, and by patents, is in effect a kind of property created by law for the benefit of an author or inventor, and which he could not effectually acquire or secure without the aid of the law. Is is not, however, a monopoly in any sense in which that term has ever been used. Whether it is profitable or injurious to the community it is a question that concerns legislation.

MONOSTEARIN. [STEARIC ACID.]

MONOSYLLABLE. [SYLLABLE.]

MONSOON (in French *mousson*), is a term applied to the periodical winds of the Indian Ocean, and, according to Marsden, is a corruption of the word *mosseem*, which, both in Arabic and Malay, signifies a year. These winds have from the earliest times attracted the attention of the navigator, as, by taking advantage of their regular blowing, an easy and speedy voyage may be calculated upon with certainty; whilst, by contravening their force, the voyage is rendered laborious, slow, and uncertain.
